New USCI, unshocked quadripolar catheters in our study had dielectric strength between 2,200 and 3,500 V. The delivered peak voltage during a shock to quadripolar catheters using a 200-J discharge ranged between 2,500 and 3,200 V. For a 360-J discharge it was between 3,900 and 4,200 V. Clearly, the possibility to exceed a catheter's maximally tolerated voltage is present during the first shock. For all the catheters studied, the dielectric strength after 1 shock was less than 2,200 V in 19 of 24 (79%) instances and was less than 1,000 V in 13 (54%). This implies an even greater likelihood of misdirected shocks for catheters used more than once. The deterioration in catheter dielectric strength to a value far less than originally present probably results from structural changes in the insulation during the initial shock.

Inappropriate current discharge was documented during the first shock in 7 catheters. In these catheters, unconnected nonanodal electrodes demonstrated pitting (platinum melting) on their surfaces, indicating that part of the current exited elsewhere than originally intended (Fig. 1). In the case of AV node/His bundle ablation, such current leakage probably will not cause any unwanted cardiac damage. The distal electrode is usually used in these instances, and therefore, an inappropriate current discharge through a more proximal electrode is unlikely to affect vital tissue, because the current leak will probably enter the atrial cavity and be dissipated in the blood. Such an occurrence, however, will result in a diminution in current at the tip electrode and therefore may not be adequate to damage the AV node/His bundle to create heart block. This may account for failure of the technique in some instances, especially with newer model USCI catheters.[1]

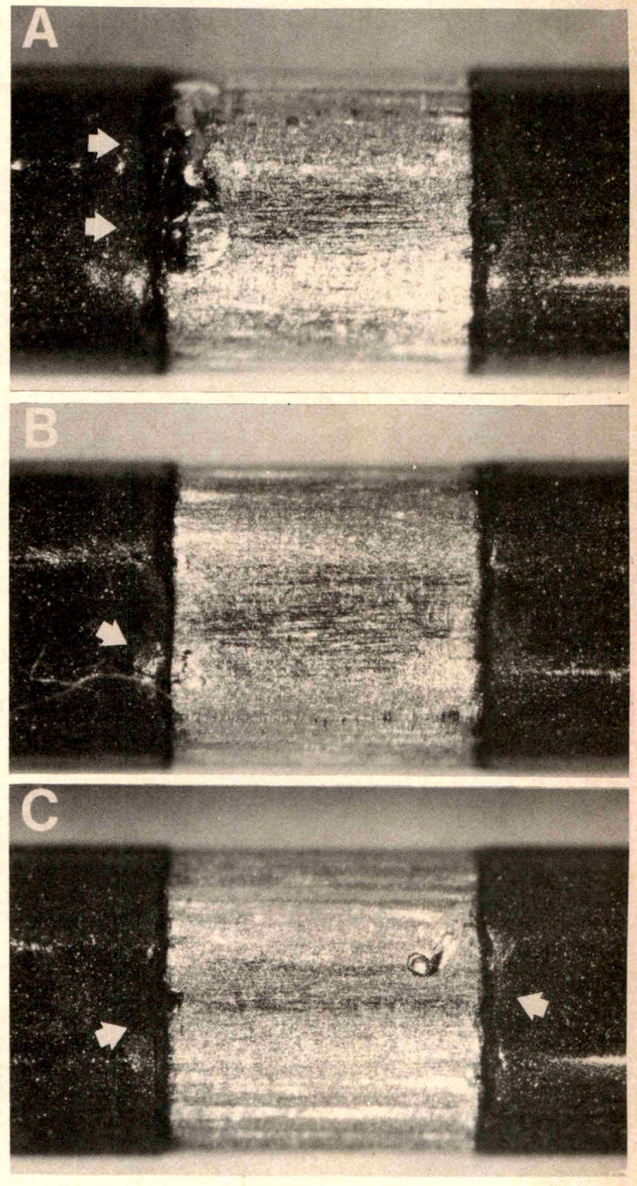

FIGURE 1. Electrode pitting (platinum melting) is designated by **white arrows** on 3 of the 4 poles of a standard 6 Fr U.S. Catheter Instruments quadripolar catheter after a single 360-J shock (peak voltage of 4,000 V and peak current of 32 A). Poles 4 and 3 served jointly as the anode (positive electrode), as might be done during at attempted posterior septal accessory pathway ablation. Pitting is seen on pole 4 (**A**) and pole 3 (**B**) as would be expected. Pitting is much more pronounced on pole 4, possibly indicating asymmetric current flow. The unanticipated pitting on pole 2 (**C**) indicates inappropriate electrical discharge through this electrode, which was not intended to serve as a part of the anodal configuration. Line resistance for pole 2 was not measurable (i.e., an open circuit). Dielectric strength after the shock was only 70 V. Pole 1 was intact and is not shown

Misdirected currents in the coronary sinus may have more significant untoward effects. Current leakage during posteroseptal accessory pathway ablation attempts could result in damage to parts of the AV groove away from the intended accessory pathway. This is a particular concern with respect to coronary artery injury. Patients considered for catheter ablation procedures should be those with no significant coronary artery near the accessory pathway. An inappropriate discharge 1 to 2 cm away from the intended delivery site might result in coronary artery injury. Furthermore, as with AV node/His bundle ablation, current leakage may result in failure of the technique to interrupt accessory AV conduction.

The concerns expressed for AV node/His bundle and accessory pathway ablation also exist for shocks delivered to ventricular tachycardia foci. Undesired current discharge might result in failure of the procedure or in damage to normal myocardium not intended to be injured.

Simple means of monitoring quality of catheter insulation for the electrophysiologist are not available. Delivering high-energy defibrillator shocks to standard catheters may result in misdirected currents with the first shock. Furthermore, one must assume that catheter insulation deteriorates after a single 200-J or higher energy shock making multiple shocks to the same catheter ill-advised. Leakage of current to "unsolicited" anodal electrodes may result in failure of the technique or an undesired outcome. Catheter technology must be improved before catheter ablation procedures can be refined or an alternative form of energy delivery will be required.

Value of Intraoperative Left Ventricular Microbubbles Detected by Transesophageal Two-Dimensional Echocardiography in Predicting Neurologic Outcome After Cardiac Operations

ERIC J. TOPOL, MD, LINDA S. HUMPHREY, MD, A. MICHAEL BORKON, MD, WILLIAM A. BAUMGARTNER, MD, DEBRA L. DORSEY, BRUCE A. REITZ, MD, and JAMES L. WEISS, MD

To determine whether the presence or absence of left ventricular (LV) intracavitary microbubbles during cardiac surgery predicts neurologic sequelae, 82 patients undergoing cardiac surgery were studied using transesophageal 2-dimensional (2-D) echocardiography. Cross-sectional images were recorded just before and immediately after cardiopulmonary bypass and stop frames were reviewed for the presence of microbubbles, rated as: 0 = absent, 1 = fewer than 5/frame, 2 = 10 to 25/frame, 3 = too numerous to count. Microbubbles were detected after cardiopulmonary bypass in 34 patients (41%) and found more often in valvular or other intracardiac manipulations than in coronary revascularization, 30 of 40 vs 4 of 42, respectively ($p < 0.001$). When grade 2 or 3 microbubbles were identified (22 of 34 patients), mechanical attempts to eradicate them were not successful. Postoperative follow-up in all patients revealed no new focal neurologic deficits. Prolonged encephalopathy (confusional state more than 72 hours) occurred in 4 of 48 patients with no detectable microbubbles and in 3 of 34 patients with microbubbles (difference not significant). Thus, intracavitary left ventricular microbubbles are often detected during cardiac operations, particularly during valve replacement, but are not predictive of postoperative neurologic complications. This is true even if microbubbles are densely concentrated; attempts to eradicate microbubbles are unsuccessful and may be unnecessary.

(Am J Cardiol 1985;56:773–775)

The origin of central nervous system complications during open heart surgery often is not known.[1] Of the many potential causes, air embolism during cardiac surgery is particularly dreaded because this complication is often avoidable. Recently, 2-dimensional (2-D) echocardiography has been used to detect left ventricular (LV) intracavitary air by means of the distinctive sonographic appearance of microbubbles. With use of this intraoperative technique, a high prevalence of intracardiac microbubbles has been shown after cardiopulmonary bypass is discontinued.[2] Although microbubbles can be detected easily with ultrasound techniques,[3–5] their clinical significance is not known.

We previously reported on the safety and ease of transesophageal echocardiography for obtaining high-quality cross-sectional images throughout the operative procedure.[6,7] Using this imaging modality, we determined whether the presence or absence of LV intracavitary microbubbles during cardiac surgery predicts neurologic outcome.

Methods

Before surgery, 82 patients undergoing various types of cardiac surgery (Table I) gave informed consent for intraoperative transesophageal echocardiography. After induction of general anesthesia and tracheal intubation, a flexible gastroscope with a miniature 3.5-MHz phased-array transducer at its tip (Diasonics) was introduced into the esophagus. Cross-sectional LV images were obtained at the level of the papillary muscles and the mitral valve before and immediately after cardiopulmonary bypass. The images were recorded and stop frames were reviewed in order to quantify the maximal number of LV intracavitary microbubbles per frame. Microbubbles were identified as small, oblong, highly mobile, echodense particles (Fig. 1). We used the same rating system as Rodigas et al[2]: 0 = absent, 1 = fewer than 5/frame, 2 = 10 to 25/frame, and 3 = too numerous to count (Fig. 1).

Before discontinuing cardiopulmonary bypass, when grade 2 or 3 microbubbles were identified, attempts to manually

TABLE I Detection and Grading of Microbubbles by Transesophageal Echocardiography

Operation	Grading of Microbubbles 0	1	2	3	No. of Pts

Intracardiac*	10	7	10	12	39
Total	48	12	10	12	82

* Microbubble detection significantly increased in intracardiac (29 of 39) vs extracardiac (5 of 43) procedures, $\chi^2 = 33$, $p < 0.001$.
ASD = atrial septal defect repair; CABG = coronary artery bypass grafting; PFE = removal of a papillary fibroelastoma; TOF = correction of tetralogy of Fallot.

de-air the left ventricle were made. Repetitive, direct manual LV compression was applied throughout the period immediately before termination of cardiopulmonary bypass. In patients undergoing only saphenous vein bypass grafting, no direct venting of the ventricle was performed, but all of these patients had left-sided cardiac decompression accomplished by means of the pulmonary artery.

Patients were followed prospectively for the development of any focal or generalized neurologic deficits in the prehospital discharge period. Neurologic examination was performed by either the house officer, an investigator or a consulting neurologist when appropriate. Charts were concurrently reviewed in order to ascertain the details of any neurologic complication.

Results

Immediately after cardiopulmonary bypass, microbubbles were detected in 34 of 82 patients (41%). Grade 2 or 3 LV microbubbles were detected in 22 patients (27%). None of the patients undergoing aortocoronary bypass surgery had grade 2 or 3 microbubbles and only 4 patients had grade 1 microbubbles identified. In contrast, intracardiac procedures such as valve replacement, atrial septal defect repair, LV aneurysmectomy, congenital defect repair and resection of an endocardial tumor were associated with a relative preponderance of dense microbubbles, with grade 2 or 3 present in 22 of 39 patients (56%). The other procedure included in this series was a pericardiectomy, which was accompanied by detection of grade 1 microbubbles. These results are summarized in Table I.

The incidence of microbubble detection in the immediate postoperative period was significantly higher among those undergoing intracardiac procedures compared with those undergoing extracardiac procedures: 29 of 39 patients (74%) vs 5 of 43 patients (12%), respectively ($\chi^2 = 33$, $p < 0.001$).

Intraoperatively, manual attempts to eradicate residual air were unsuccessful in all 22 patients who had grade 2 or 3 microbubbles. Success was defined as complete eradication of microbubbles. The grade was reduced by at least 1 in 13 of 22 patients in this group.

Postoperatively, neurologic follow-up data revealed no new focal deficits in any study patient. Before entry in the study, 12 patients had sustained a neurologic event, either a stroke or transient ischemic attack and 2 patients had a history of grand mal seizures. After surgery, a generalized encephalopathy, or acute confusional state,[8] was present in 7 patients and lasted from 3 to 5 days. The generalized deficit occurred in 4 of 48 patients in whom no microbubbles were detected and 3 out of 34 patients with intraoperative microbubbles (difference not significant). Detailed chart review of these 7 cases failed to reveal a clearcut origin for the

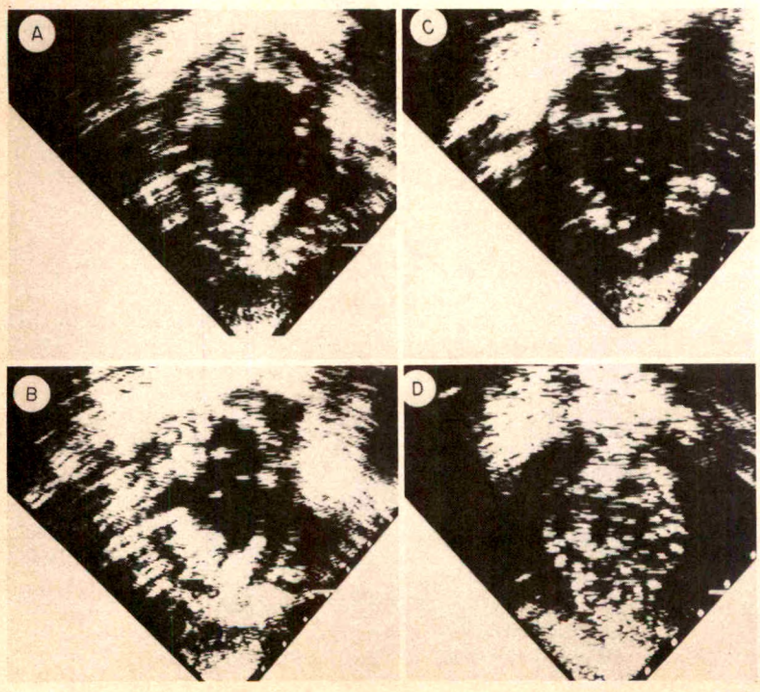

FIGURE 1. Grading of intracavitary left ventricular microbubbles in stop-frame cross-sectional echocardiograms, at the mid–papillary muscle level, recorded during cardiac surgery. Microbubbles are demonstrated as small, oblong, echodense particles within the cavity. **A,** grade 0—microbubbles are absent. **B,** grade 1—fewer than 5 microbubbles per frame. **C,** grade 2—10 to 25 microbubbles per frame. **D,** grade 3—too many microbubbles to count.

encephalopathy. Each patient had been treated with a variety of medications, anesthetic agents and transient hypotension in the 24 hours after surgery. Thus, it remains unclear whether cerebral air embolism in any way caused the generalized neurologic deterioration that occurred in these 7 patients.

Discussion

Avoidance of major central nervous system complications after cardiac surgery, which occur in approximately 5% of patients undergoing such procedures,[1,9] is an essential goal. Without question, air embolism from the LV cavity is responsible for some postoperative strokes. Using transesophageal 2-D echocardiography, we have shown that microbubbles are often detected immediately after cardiac surgery, particularly valve replacement and other intracardiac procedures. However, attempts to eradicate the microbubbles were unsuccessful and despite an extremely high density of intracavitary bubbles in some patients, gross neurologic deficits did not occur postoperatively in any study patient. Our results related to the high incidence of LV microbubbles are in agreement with those of Rodigas et al.[2] In their study, of 79 patients undergoing a variety of cardiac procedures, in 49 patients (62%) microbubbles were present, more often in valve replacement cases. In no patient did a gross neurologic deficit develop postoperatively. In contrast to their study, however, continuous transesophageal 2-D echocardiography after cardiopulmonary bypass allowed us to monitor attempts to remove the microbubbles. Furthermore, our study was designed to consider neurologic outcome and we prospectively identified 7 patients with encephalopathy, which may have been related to cerebral air embolism.

The lack of a stroke or new focal deficit in both series, despite finding high-grade intracavitary microbubbles in 26% of patients, raises the issues of the sensitivity and clinical significance of microbubble detection. The considerable body of work in the field of contrast echocardiography suggests that microcavitation or microbubbles do indeed represent air.[10–12] Certainly, the preponderance of microbubble detection after intracardiac procedures, which allow the introduction of air into the left ventricle, confirms this hypothesis.[2] If air is frequently present in the left ventricle after cardiopulmonary bypass, why aren't there more clinical sequelae observed? Several explanations are possible. First, some studies suggest that 2-D echocardiography is so sensitive in the detection of microbubbles as to lead to false-positive diagnoses. Although this would be expected for grade 1 microbubbles, it is difficult to imagine that either grade 2 or, especially, grade 3 microbubbles represent false-positive findings. Second, it is possible that air is, in fact, embolized, but these 2- to 100-μ particles[3–5] may be cleared from the circulation without significant loss of perfusion. Feinstein et al[13] showed in an experimental study that microbubble size plays a critical role in their passage through the capillary bed and that large microbubbles coalesce, temporarily obstruct flow and subsequently shrink or collapse. The third possible explanation relates to the underdiagnosis of a clinical event, in this case extremely more subtle neurologic deficits, which have not been prospectively related to microbubble embolization. This represents a limitation of the current study, which did not ascertain long-term neurologic follow-up or include specific objective psychological or cognitive testing.[14] Recent studies suggest that post–cardiopulmonary bypass neurologic damage may be subclinical.[15,16] However, no study patient evinced any focal neurologic deficit postoperatively.

Implications: Transesophageal 2-D echocardiography is safe and relatively easy to perform intraoperatively. Owing in part to its ability to detect microbubbles, it has been suggested that this technique, or direct 2-D echocardiography from the epicardial surface, be applied widely to patients undergoing not only cardiac but also neurosurgical procedures.[17–19] The present study points out that even dense intracavitary LV microbubbles so detected may not predict an adverse postoperative clinical neurologic outcome. Further, the presence of microbubbles after intracardiac procedures is not significantly affected by manual attempts to eradicate them. Such attempts may be unnecessary, because in keeping with the results of Rodigas et al,[2] no data support their clinical significance.

Right Ventricular Ejection Fraction Measured by First-Pass Intravenous Krypton-81m: Reproducibility and Comparison with Technetium-99m

DEAN F. WONG, MD, T.K. NATARAJAN, DRE, ScD, WARREN SUMMER, MD, PAUL A. TIBBITS, MD, THOMAS BECK, MS, DANIEL KOLLER, CNMT, WAYNE KASECAMP, CNMT, JAMES LAMB, PhD, JOSEPH OLYNYK, MARY SUE PHILP, MARSHALL BRYAN, MPH, and HENRY N. WAGNER, Jr., MD

Study of the effects of various diseases and therapeutic manipulation of pulmonary vascular resistance on the right ventricle has been restricted by methodologic limitations. The radioactive gas in solution, krypton-81m was used to study the right ventricle and the technique was compared with a technetium-99m method. In 22 subjects, first-pass krypton-81m right ventricular ejection fraction, acquired both in list mode and electrocardiogram-gated frame mode, correlated well (r = 0.81 and 0.86, respectively, p <0.01) with that determined by technetium-99m first-pass studies over a broad range of ventricular function. The reproducibility of the technique was excellent (r = 0.84 and 0.95 for each acquisition mode, respectively). Krypton-81m first-pass studies provide accurate and reproducible estimates of right ventricular function. Use of krypton allows multiple measurements, with or without perturbations, over a short period of time.

(Am J Cardiol 1985;56:776–780)

Studies of right ventricular (RV) performance in patients with coronary artery disease,[1,2] congenital heart disease[3] and chronic obstructive pulmonary disease[4] have been performed since 1951. The proliferation of pharmacologic means to manipulate pulmonary vascular resistance with agents such as oxygen, hydralazine, nitrates and, most recently, nifedipine makes assessment of RV function timely.[5–10] Echocardiography and contrast angiography are not adequate for this application. Radionuclide methods using technetium-99m have been used to study the right ventricle,[2] but have been limited by background accumulation with first-pass methods; the presence of tracer in the left ventricle with the equilibrium method has made accurate assessment of the activity within the right ventricle difficult. We studied a new method, using intravenous krypton-81m, for assessment of RV function to obviate these difficulties.

Methods

Twenty-two subjects were studied: 7 normal volunteers, 13 patients with chronic obstructive lung disease and 2 patients with primary pulmonary hypertension. Each subject underwent multiple first-transit krypton-81m studies (see later), with injection into an antecubital vein from a rubidium-81/krypton-81m generator. The generator consisted of the parent, rubidium-81 (half-life = 4.5 hours, total activity of the generator 15 to 20 mCi), fixed on a macroporous cation exchange resin (AGMP-50 resin column). The daughter, krypton-81m (half-life 13 seconds), was eluted continuously in 5% dextrose in water (low free-ionic content) at a rate of 20 to 30 ml/min using a Masterflex rotary tube pump. A cold scavenger resin column was included between the generator and the patient to reduce the rubidium breakthrough reaching the patient to a minimum (see Radiation dosimetry section). The patients were placed in the 30° right anterior oblique position. The first transit of krypton-81m was imaged with a gamma camera with a 200-keV, parallel-hole collimator interfaced to a dedicated minicomputer. Two methods of computer acquisition were used: list mode and electrocardiogram-gated first-pass frame mode.

For the list mode technique, data collection started when the rotary pump was turned on and continued until activity reached the lungs, the approximate duration being 30 to 50 seconds. A series of images was created from the list mode data that identified the right atrium, right ventricle and pulmonary artery. The operator drew a rough region of interest around the right ventricle. A high-frequency time-activity curve (30 ms/point) was derived. End-diastole for each beat was defined as the peaks and end-systole as the troughs of the time-activity curve. A 16-frame composite cardiac cycle was created using only the frames showing activity in the right ventricle.

In the electrocardiogram-gated frame mode procedure, the acquisition was 20 to 40 seconds, beginning when activity was first noted in the superior vena cava on the persistence scope. Acquisition was terminated when activity reached the lung fields. Two regions of interest (end-diastolic and end-systolic) were used in calculating the RV ejection fraction.

Total body*	—	9.1×10^{-3}	0.025	0.014	0.048

* Includes ^{81}Rb breakthrough of 0.15 μCi/mCi ^{81}Rb-min.
— = not computed.

End-diastolic, end-systolic, and background-count regions of interest were drawn with the assistance of phase and amplitude images. Ejection fraction was calculated as [(RVED − RVES)/RVED] × 100 where EF = ejection fraction, RVED = the background-corrected counts in the end-diastolic region of interest, and RVES = the background-corrected counts in the end-systolic region of interest.

Each subject underwent 1 list mode and/or 1 gated frame mode study and at least 1 replicate study of each technique within 2 to 3 minutes of the first acquisition. In 17 patients, repositioning between acquisitions was performed by deliberately moving the patient out from the camera to test the limits of reproducibility.

Each patient underwent a first-pass technetium-99m pertechnetate (15 to 20 mCi) study in the right anterior oblique 30° position within 24 hours after the krypton-81m studies.

Radiation dosimetry: The assumptions were for conservative dose estimation. The generator was assumed to be eluted with an efficiency of 90% and free of radionuclidic impurities. Transit time from generator to infusion site was assumed to be 5 seconds, yielding a total correction factor for activity delivered of 0.689. No correction for decay during vascular transit in vivo was used. Krypton-81m activity was assumed to be eluted at rate of production. Therefore, including the branching of rubidium-81 to krypton-81, the production/elution rate was 51.1 μCi of krypton-81m per millicurie of rubidium-81 per second. The corrected delivery rate was then 2.11×10^3 μCi of krypton-81m per millicurie of rubidium-81m per minute of infusion. At the infusion site, blood and infusate were assumed to be instantaneously mixed. Assuming blood flow at the infusion site to be 760 ml/min, the instantaneous activity concentration was then 2.93 μCi/ml/mCi of rubidium-81. All infused activity was assumed to enter the lung by way of pulmonary circulation. For organ exposure estimation, recirculation was ignored, whereas for total body exposure, 2% of the administered activity was assumed to remain in circulation. Effective washout halftimes for lung and whole body were assumed to be 9 and 13 seconds, respectively.

The dose values are listed in Table I. The rubidium generator was typically 15 to 20 mCi.

Infusion times were usually 30 seconds (maximum 1 minute). This gives a typical dose of about 50 mrads to the infusion site and less than 18 mrads to lung and 8 mrads to heart per first-pass study. For assessment of the radiation exposure from rubidium-81 "breakthrough" in intravenous administration of krypton-81m, it was assumed (worse case) that for a 15-mCi generator and 300 ml of eluent delivered, the total rubidium-81 activity administered was 45 μCi. The assumption was based on measured breakthrough ranging from 0.1 to 4.2 μCi/100 ml eluent for generators 5 to 20 mCi in size. Assuming instantaneous uptake, uniform distribution whole body, and no biologic elimination, radiation doses from rubidium-81 were computed using "S" factors.[11–14] Dose estimates also included contribution from daughter krypton-81m. Typical dose estimates of breakthrough (for flow rate 30 ml/min) for a minute first-pass study are listed in Table II. For this preliminary study, a cold resin column was positioned in the infusion line to preclude any rubidium-81 breakthrough from reaching the patient. However, these dose estimates showed that this precaution is probably not necessary for the use of this generator for dose reduction and may serve only as a "worst case" downstream trap in the unlikely event of severe resin breakthrough (as in an accidental elution with NaCl, which would strip the column).

TABLE II Dosimetry Breakthrough for Typical Study*

Organ	Total Dose
Testes	0.4 mrad
Ovaries	0.64 mrad
Active marrow	0.57 mrad
Total body	0.58 mrad

* Assuming 4.5 μCi rubidium-81/30 ml eluent.

Results

A typical study of RV ejection fraction is shown in Figure 1. The data were analyzed as follows (Fig. 2–4): (1) list mode acquisition of krypton-81m vs list mode for technetium-99m pertechnetate; (2) gated frame mode krypton-81m vs list mode technetium-99m pertechnetate; (3) correlation between krypton replicates for all subjects; (4) correlation between list mode or gated frame mode krypton replicates using only studies with repositioning; and (5) krypton list mode vs gated frame mode.

The correlation and the number of data pairs for the different methods of analysis are listed in Table III. The mean of all replicates (33 for list mode; 30 for frame mode) for each patient was used for correlation with technetium-99m pertechnetate RV ejection fraction. The list mode and gated frame mode krypton-81m techniques agreed equally well with the technetium-99m RV ejection fraction ($r = 0.81$, $p < 0.01$, Fig. 2 left, and 0.86, $p < 0.01$, Fig. 2 right, respectively).

The 99% confidence intervals are shown about the regression lines in Figure 3 for the plot of the list mode krypton-81m vs gated frame mode results for all patients who had both studies; the results are averaged over replicates for each technique. The correlation was excellent ($r = 0.88$, $p < 0.01$).

For each mode we assessed the reproducibility by presenting the correlation between pairs of measurements, each pair from a different subject. Because each

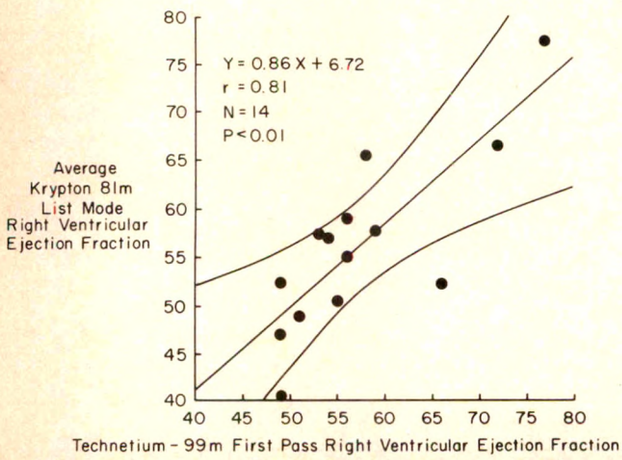
Avg. = average; FM = frame mode; GFM = gated frame mode; Kr = krypton-81m first-pass right ventriculogram; LM = list mode; Tc = technetium-99m.

subject had multiple measurements (38 for list mode, 22 for frame mode), we used a randomization method to construct a distribution of correlation coefficients: From the data on each subject, we randomly selected 1 pair of measurements and computed the correlation coefficient for all subjects. This procedure was repeated 1,000 times. The histogram (Fig 4) of correlation coefficients was used to define the 95% confidence limits on the reproducibility correlations (Table III and IV). The correlations in the 17 patients for whom a single camera-repositioning replicate was available are listed in Table III.

The paired replicates for all possible combinations are shown in Figure 3 for the list mode and the gated frame mode techniques. There was excellent reproducibility, even when correlation of replicates was limited to those with repositioning (Table III, r = 0.95 and 0.98, respectively). The average coefficients of variation over all patients for each technique of acquisition (4.5% and 3.2% for list mode and gated frame mode, respectively) are listed in Table IV, confirming the excellent reproducibility of both techniques.

Discussion

Early studies to evaluate RV performance used indicator dilution techniques, including dye,[15] thermal[16] and radionuclide[17] methods. Contrast ventriculography has been used since 1967 to obtain RV volumes.[18] However, contrast angiography must rely on various geometric models of RV shape,[19] and requires correction by regression equations for systematic overestimation



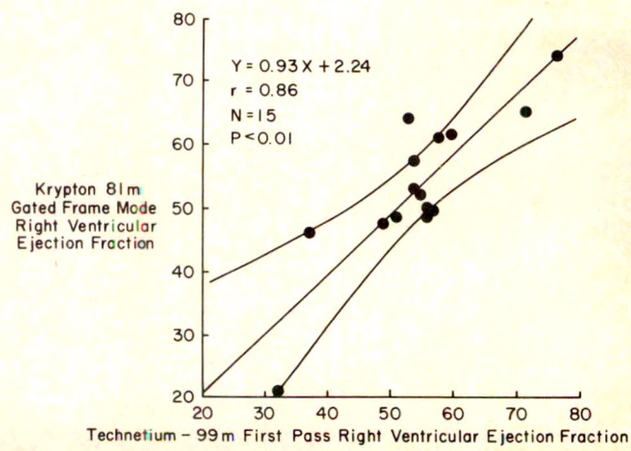


FIGURE 2. Comparison of the 2 krypton-81m acquisition methods with the technetium-99m pertechnetate method. The krypton estimates were averaged for a given patient. The linear regression line was plotted with 99% confidence limits. **Left,** average krypton-81m list mode right ventricular ejection fraction vs technetium-99m list mode right ventricular ejection fraction. The correlation between the average krypton and technetium pertechnetate estimates of right ventricular ejection fraction is 0.81 ($p < 0.01$). **Right,** average krypton first-pass electrocardiogram-gated frame mode right ventricular ejection fraction vs technetium-99m list mode right ventricular ejection fraction.

of RV volume. Because of the difficulty of geometric modeling and the invasive nature of angiography, study of the right ventricle with this method has been of little value in adults.

Echocardiography has had limited usefulness in study of the right ventricle. M-mode echocardiography cannot fully delineate the irregular shape of the right ventricle because of the small area sampled by this technique.[20,21] No specific geometric model has been predictive of volume from the axes measured by 2-dimensional echocardiography.[21]

Several methods have been developed using gated blood pool techniques.[22] The use of slant-hole collimator has been advocated as a refinement of the equilibrium method.[23] However, with all of these methods, the underlying assumption has been that overlap of the right ventricle with the right atrium was not significant.

Steele et al[24] used first-pass technetium-99m to measure ejection fraction. This method had a correlation of 0.8 with contrast angiography,[25] and has remained the standard method of assessing performance in most clinics. To obtain repeat studies using first-pass techniques, Berger et al[26] used rapidly cleared technetium ligands. However, accumulation of background activity limited the number of first-pass studies that could be obtained in a single sitting. Radiogold-195m has also been used similarly. It is not eliminated by the lungs, and thus appears in the left ventricle, which interferes with RV study.[27] The use of radioactive gases that clear rapidly from the lungs for first-pass measurement of RV ejection fraction has the advantage of little background accumulation and isolation of the radionuclide to the right side of the heart. Goldberg et al[28] showed good agreement of intravenous xenon with technetium-99m first-pass studies. Krypton-81m has the additional advantage of a 13-second half-life, allowing rapid clearance of isotope, resulting in low radiation exposure and background activity. Knapp et al[29] performed list mode intravenous krypton studies of the right ventricle, but did not validate the accuracy of the method.

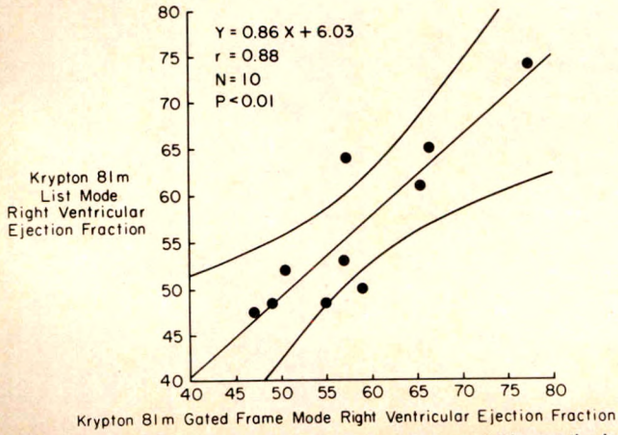

FIGURE 3. Comparison of both krypton computer acquisition methods. In 10 patients in whom both list mode and gated frame mode studies were obtained, the average right ventricular ejection fraction for the gated frame mode vs the list mode is plotted.

TABLE IV Reproducibility

Acquisition	No. of Pts.	No. of Studies	Average Coefficient of Variation	1 SD
LM	14	37	4.55	3.62
FM	12	28	3.23	1.96

* CV = (SD/mean) × 100% for each patient.
FM = gated frame mode; LM = list mode; SD = standard deviation.

We found good correlation between the krypton-81m and technetium-99m pertechnetate first-pass studies. The correlation was equally good for krypton studies acquired by list mode or electrocardiogram-gated frame mode. Both acquisition techniques have advantages and limitations. The list mode allowed selective beat-to-beat determination of RV ejection fraction. List mode was operator-independent, in that precise timing of start and termination of acquisition was not necessary. In gated frame mode, however, accurate timing of the transit to the pulmonary artery was required to exclude the pulmonary phase from the present framing sequence. Because the list mode in this study did not include the R wave from the electrocardiogram, the linkage of the R wave to the gated frame mode allowed exact identification of the end-diastolic frame, whereas the list mode method used the peaks of the time-activity curve. The gated frame mode technique was somewhat more technically reliable for krypton studies (91% for gated frame mode vs 74% success for list mode). Frame mode required less computer space and processing time than list mode.

The excellent reproducibility and rapid repeatability with krypton were a result of prompt removal of tracer by the lungs, the short half-life, and rapid regeneration of the daughter by the parent generator. The method was easily performed and highly reproducible even after repositioning. Rapid regeneration of activity in the generator allowed replicate acquisitions every 1 to 2 minutes.

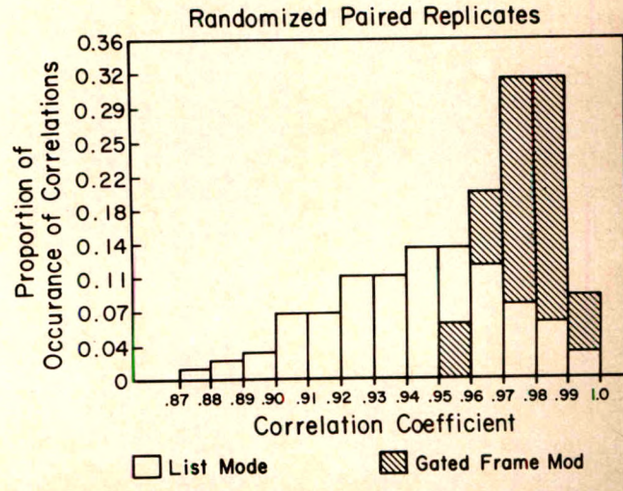

FIGURE 4. Reproducibility studies. The result of randomly pairing replicates is shown as histograms of correlation coefficients. The peak distribution of the gated frame mode (**hatched bars**) is slightly higher (r = 0.98) than the list mode (**open bars**) peak correlation (r = 0.95).

The radiation dose from first-pass krypton was small compared with first-pass technetium-99m pertechnetate (Table I). Even for 10 replicate studies, radiation dose was low, with the maximal dose to the skin at the intravenous site, which is a radioresistant area.

The only inconvenience of intravenous krypton was the short half-life of the parent, rubidium-81 (4.5 hours), limiting useful generator lifespan to 1 day. However, rubidium-81 is cyclotron-produced for ventilation generators in the U.S. 5 days a week, and could become more available for intravenous use in the future. The imaging characteristics of krypton-81m were excellent (photopeak 190 keV), allowing use of a medium-energy (or high-rated, low energy) collimator increasing count-density information without significant loss of resolution. The high energy level of radiogold-195m is not well suited to gamma camera imaging, and requires a high-energy collimator, which decreases resolution significantly.

Acknowledgment: We are grateful to P.D. Wilson and V. Dave for their special assistance.

Give enough to do the job

ISORDIL®
(ISOSORBIDE DINITRATE)

Contraindications: Hypersensitivity or idiosyncrasy to this drug or other nitrates or nitrites.
Warnings: Benefits of use during the early days of an acute myocardial infarction have not been established; if used in early infarction, hemodynamic monitoring and frequent clinical assessment should be made because of the potential deleterious effects of hypotension.
Precautions: *General.* Severe hypotensive response, particularly with upright posture, may occur even with small doses; therefore use caution in subjects with blood volume depletion from diuretic therapy or with low systolic blood pressure (eg, below 90 mm Hg). Paradoxical bradycardia and increased angina pectoris may accompany nitrate-induced hypotension. Nitrates may aggravate angina caused by hypertrophic cardiomyopathy. Tolerance to this drug and cross-tolerance to other nitrates and nitrites may occur. Marked symptomatic, orthostatic hypotension has been reported when calcium channel blockers and organic nitrates were used in combination; dose adjustment of either class of agents may be necessary. There are reports of anginal attacks being more easily provoked and of rebound in hemodynamic effects soon after nitrate withdrawal; when therapy is being terminated, withdraw the drug gradually rather than stopping it abruptly.
Information for Patients. Headache may occur during initial therapy; it is usually relieved by standard headache remedies, or by lowering the dose, and tends to disappear after the first week or two of use.
Drug Interactions. Alcohol may enhance any marked sensitivity to the hypotensive effect of nitrates. Isosorbide dinitrate acts directly on vascular smooth muscle; therefore, any other agent that depends on vascular smooth muscle as the final common path can be expected to have decreased or increased effect, depending on the agent.
Carcinogenesis, Mutagenesis, Impairment of Fertility. No long-term studies in animals have been performed.
Pregnancy Category C. Use during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Nursing Mothers. It is not known whether this drug is excreted in human milk; because many drugs are excreted in human milk, caution should be exercised in nursing women.
Pediatric Use. Safety and effectiveness in children have not been established.
Adverse Reactions: Adverse reactions, particularly headache and hypotension, are dose related. At various doses, the following have been observed:
Headache is the most common (average occurrence about 25%) and may be severe and persistent. Cutaneous vasodilation with flushing may occur. Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop (the incidence of reported symptomatic hypotension ranges from 2% to 36%). An occasional individual will exhibit marked sensitivity to the hypotensive effects of nitrates, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration, and collapse) may occur even with the usual therapeutic dose. Drug rash and/or exfoliative dermatitis may occasionally occur. Nausea and vomiting appear to be uncommon.
Overdosage: *Treatment.* Prompt removal of the ingested material by gastric lavage is reasonable but not documented to be useful. Keep the patient recumbent in a shock position and comfortably warm. Passive movements of the extremities may aid venous return. Administer oxygen and artificial respiration if necessary. If methemoglobinemia is present, administer methylene blue (1% solution), 1 to 2 mg/kg intravenously. *WARNING:* Epinephrine is ineffective in reversing the severe hypotensive events associated with overdose. It and related compounds are contraindicated in this situation.
Consult direction circular before prescribing.

If you like what you're reading, you'll love what you'll be watching

The American Journal of Cardiology does more than just print the best in authoritative articles on cardiovascular treatment. Now it puts them on videotape.

Hosted by Editor-in-Chief William C. Roberts, MD, *AJC Video Report* will feature lively, highly-visualized discussions with noted cardiovascular specialists and authors of the most important articles appearing each month in *The American Journal of Cardiology.* And it will extend the utility of the articles by exploring their application in clinical practice.

Each of the 45 minute videocassettes will feature a special guest panelist as well as the guest authors discussing:

• Coronary Heart Disease • Arrhythmias and Conduction Disturbances • Systemic Hypertension • Congestive Heart Failure • Valvular Heart Disease • Cardiomyopathy • Congenital Heart Disease • Cardiovascular Pharmacology and • Experimental Studies

AJC Video Report will be produced on a regular monthly basis starting January, 1986.

TO RECEIVE every copy of AJC Video Report—at the special introductory subscription price of $395* for 12 cassettes—complete this coupon and send it to: Joyce Sturges, *AJC Video Report,* The Yorke Medical Group, 875 Third Avenue, New York, N.Y. 10022. Or call (212) 605-9549.

The American Journal of Cardiology

Our specialty is homecomings.

We know all patients enter a hospital with one wish. To go home.

It's a wish we share with them.

That's why at Sinai, we've developed one of the world's most technically advanced cardiac care units, and staffed it with some of the foremost heart specialists. Last year alone we performed over 500 open heart surgeries.

In our neonatal intensive care unit, we've brought together the best features of the country's leading infant care units. And last year saved the lives of 351 critically ill newborns.

Through vigorous research, we've pioneered dozens of new diagnostic techniques.

All our work is for one reason. To allow our patients to go home. And last year, we're proud to say, we made possible 23,766 homecomings.

For further information or doctor referral, call Sinai Hospital, 493-5500.

Color comes to cardiac. And imaging has never looked better.

Until recently, fast accurate measurement, in real time, of blood flow and gradient was not possible by noninvasive means. Color Doppler analysis has changed this dramatically.

Toshiba's SSH-65A makes use of the Doppler Effect, whereby direction of flow produces changes in frequency, visible in gradations from red to blue. Flow abnormalities, for example regurgitations, are shown as color coded profiles and their severity can be quantified using the FFT-doppler spectrum.

A single unit offers total cardiac phase study, through two-dimensional real-time blood flow imaging; quantitative blood analysis in any ROI, through Pulsed Wave Doppler; and measurement of high blood flow by Continuous Wave Doppler.

The high resolution of the images naturally meets Toshiba's exacting requirements.

Never before has the invisible been rendered so visible!

The most important, best read annual publication on cardiology

What is CARDIOLOGY 1985?

- The fifth in an annual series to be published each summer—761 papers covered in this issue.
- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, **written,** not just edited, by those making outstanding contributions in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1985 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly accessible knowledge.

Reviews of previous editions

". . . recommend . . . to any reader interested in the literature of cardiology."
Irwin R. Callen, MD
JAMA

". . . It is more than merely a reference book, since it explains what to the average physician may be obscure . . . a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, MD
New York State Journal of Medicine

"I highly recommend this book as a reference for cardiologists and general internists who wish to review specific topics in the recent cardiology literature. The summaries are generally concise and well written and the choice of articles reviewed is superb and nicely indexed."
James L. Vacek, Major USAF, MC, FACC, FCCP
Military Medicine

"Dr. Roberts and his colleagues have done it again. . . . All in all, this is a remarkable tour de force of inestimable value to all physicians struggling to understand the heart and its problems."
David H. Spodick, MD
Practical Cardiology

Measurement of Left Ventricular Volume Using Single-Photon Emission Computed Tomography

GARY R. CAPUTO, MD, MICHAEL M. GRAHAM, PhD, MD, KIRK D. BRUST, BS, J. WARD KENNEDY, MD, and WIL B. NELP, MD

A count-based method for measuring left ventricular (LV) volume using technetium-99m-labeled red cells and ungated single-photon emission computed tomography is described. The tomographic slices were used to determine the counts per milliliter in the center of the left ventricle and total LV counts, which were used to derive mean LV volume. End-diastolic and end-systolic volumes were calculated from the mean volume using the LV time-activity curve from planar gated blood pool images. Phantom evaluation with simulated LV volumes (50 to 400 ml) in air, in a phantom filled with water, with 10% background, and with a simulated right ventricle, showed excellent accuracy. For clinical validation, 30 patients underwent electrocardiographically gated planar and nongated tomographic acquisition of the cardiac blood pool followed by single-plane cineangiography. For end-diastolic and end-systolic volumes combined, the correlation with cineangiography showed a standard error of the estimate (SEE) of 24 ml and 14 ml, respectively. Mean intra- and interobserver deviation was 12 ml and 14 ml (SEE 13 ml and 16 ml), respectively. It is concluded that this noninvasive count-based technique, requiring no assumptions regarding LV geometry, is an accurate and reproducible way to measure LV volume.

(Am J Cardiol 1985;56:781–786)

Left ventricular (LV) volume is an important measurement in the evaluation of cardiac function. Radiographic LV cineangiography is the standard method for measuring LV volume.[1,2] This method assumes the left ventricle to be a prolate ellipsoid, which may not be true in patients with regional LV dysfunction.[3] Furthermore, it is invasive, requiring intraventricular contrast injection, and is not suitable for serial volume determination. These limitations have resulted in a search for an accurate and reproducible noninvasive method for measuring LV volume. Such a method would be useful for monitoring serial changes in cardiac function and evaluating the effects of cardiac surgery and drug therapies.

M-mode echocardiography may be used to measure end-diastolic and end-systolic internal dimensions of the left ventricle. These dimensions have been used to estimate LV volume[4,5]; however these volumes may be inaccurate owing to the many assumptions required to obtain a 3-dimensional volume using a single internal dimension.[5]

Several investigators have attempted to use 2-dimensional echocardiography to calculate LV volume.[6–12] Among these approaches is the area-length technique, often used for angiographic volumes. How useful these approaches are in various pathophysiologic states remains to be determined.

Radionuclide first-pass and gated blood-pool LV volume determinations have been made using the same basic area-length method.[13–16] Although some of the limitations inherent in contrast ventriculography are avoided, precise definition of the left ventricle is difficult, and the same geometric problems remain. Any technique that attempts to calculate LV volume from data that are not 3-dimensional has limitations.

An alternate radionuclide approach is count-based analysis of planar gated blood-pool images, thus avoiding the geometric problems.[16–23] However, this method requires correction for photon attenuation, and superimposed vascular structures may contribute extraneous counts to the left ventricle.[24]

Although transmission computed tomography provides 3-dimensional cardiac data that have been used to measure LV casts,[25] conventional scanners require contrast enhancement and exposure times that may be too long for the determination of end-diastolic and end-systolic volumes in vivo.[26]

Single-photon emission computed tomography (SPECT) obviates the problem of overlying structures and should be applicable to either the geometric or count-based method for determining LV volumes.[27]

This report examines a count-based emission tomographic approach to the measurement of LV volume and extends previous work[28] with phantoms to a validation study in a series of 30 patients.

Methods

Spatial calibration: A Lucite® phantom with orthogonal point sources was used for spatial calibration. The phantom was imaged tomographically and the distance between the

points was measured using the count profiles to clearly show the location of the center of the points. These distances were used to precisely measure the voxel size in centimeters (0.68 × 0.68 × 0.66), yielding 0.305 ml per voxel.

Simulated left ventricular chamber and torso phantom: A calibrated syringe connected to a water reservoir containing 2.5 μCi/ml of technetium-99m (Tc-99m) was used to fill an ellipsoidal latex balloon used to simulate the LV chamber, in 50-ml increments from 50 ml to 400 ml. The torso phantom was a cylindrical water bath 15 cm in diameter. A similar biventricular torso phantom included an elongated 100-ml simulated right ventricular chamber separated from the LV chamber by a 1-cm-thick simulated ventricular septum.

Tomographic images: Tomographic images of the simulated LV chamber were recorded in air, in the torso phantom filled with water, water with 10% background activity by volume, and water with 10% background activity and the addition of a simulated right ventricle. The long axis of the torso phantom was parallel to the axis of rotation of the gamma camera.

For each volume measurement, images were acquired over 360° in 64 five-second increments using a GE 400A camera mounted on a 400T stand interfaced to an ADAC System 1 computer, using a 64 × 64 matrix and word mode. Preliminary ADAC software (obtained from CGR) was used for non-attenuation-corrected image reconstruction. This software provided filtered, back-projected images, but did not allow specification of the filter or attenuation correction.

Simulated left ventricular chamber volume determination: For each tomographic slice a region of interest encompassing the edge of the activity within the simulated LV chamber was defined using a light pen. The counts contained within each region of interest were measured in each slice and then summed to yield the total counts in the LV chamber. After spatially smoothing a midventricular chamber slice twice with a 9-point binomial filter, the maximal count per voxel within the region of interest was determined. This was assumed to be the count per voxel of Tc-99m at the depth of the simulated LV chamber. Using the previously determined spatial calibration factor and this count, the count per milliliter of Tc-99m solution was calculated. The simulated LV chamber volume was obtained by dividing the total counts contained in the simulated LV chambers by the count per milliliter.

Data acquisition and analysis: Data were obtained with the simulated LV chamber in air, in the torso phantom filled with water, water with 10% background activity by volume, and water with 10% background activity and the addition of a simulated right ventricle. In each case, calculated volumes were compared to the directly measured simulated LV chamber volumes and subjected to statistical analysis by linear regression.

Patients: Thirty-five patients, 30 with coronary artery disease, 2 with cardiomyopathy and 3 with valvular heart disease, underwent planar gated blood pool studies, followed by nongated tomographic acquisition of the cardiac blood pool. Twenty-two patients were men, mean age 54.6 years (range 23 to 73), with a mean height of 176.7 cm (range 160 to 188) and mean weight of 81 kg (range 55 to 104). Thirteen patients were women, mean age 60.5 years (range 38 to 72), with a mean height of 160.2 cm (range 151 to 169) and mean weight of 69 kg (range 52 to 86). The overall mean age was 56.8 years (range 23 to 73), mean height 170.6 cm (range 151 to 188) and mean weight 76.6 kg (range 52 to 104).

Five patients with coronary artery disease had technically inadequate LV cineangiograms after successful tomographic determination of their end-diastolic and end-systolic volumes and were not included in the data analysis. Seventeen patients had 1 or more areas of asynergy at rest, 9 of whom had at least 1 akinetic segment.

The average elapsed time from completion of tomographic acquisition to LV cineangiography was 2.8 hours (range 0.5 to 17). One patient underwent LV cineangiography 4 hours before tomographic acquisition.

Planar gated blood pool acquisition and analysis: Each patient received 25 mCi of in vitro labeled autologous red blood cells. A standard multigated acquisition of 90% of the RR interval was then performed in an optimized left anterior oblique projection using a GE 400A camera and an ADAC 3300 computer. A standard edge detection algorithm was used to create LV regions of interest for each of the 16 frames per cardiac cycle. These regions of interest were used to generate a time-activity curve for the left ventricle. This time-activity curve was corrected to 100% of the RR interval by interpolation of points during diastasis. From the time-activity curve, the ratios of the end-diastolic and end-systolic counts to the mean LV counts were determined.

Tomographic acquisition, reconstruction and analysis: After the gated planar study, 128 ten-second, nongated tomographic images were acquired over 360° with a total acquisition time of 22 minutes. The data were collected in word mode using an ADAC 3300 computer system in a 64 × 64 matrix. The images were spatially smoothed and high-speed tomographic reconstruction of the images was performed using ADAC software and a Butterworth filter with a cutoff frequency of 0.5 cycles per pixel, a filter order of 5, and a reconstruction matrix of 64 × 64. Tomographic reconstruction required 7½ minutes. The tomographic slices were orthogonal to the long axis of the patient's body and were not reoriented.

To avoid bias, the studies were coded so that the observers had no knowledge of the patient's identity at the time of analysis. Using a light pen, 2 observers independently created regions of interest encompassing the activity contained within the left ventricle for each LV slice. The mitral valve plane was approximated by defining a point at the junction between the muscular portion and the membranous portion of the ventricular septum. From this point, a line perpendicular to the interventricular septum intersecting the free wall of the left ventricle was drawn. This LV boundary was extended along both the ventricular septum and free wall, circling the apex to complete the region of interest (Fig. 1). A midventricular slice was spatially smoothed twice, using the standard 9-point binomial filter and the maximal count per pixel was taken as the count per voxel. The count per milliliter of blood was then calculated using the spatial conversion factor obtained previously. The counts from each LV region of interest were summed to yield the total counts obtained within the left ventricle. The total counts within the left ventricle were divided by the count per milliliter of blood to determine the mean LV volume.

Left ventricular end-diastolic and end-systolic determination: End-diastolic and end-systolic volumes were derived using the planar LV time-activity curve data. The end-diastolic volume is the mean tomographic LV volume times the ratio of the end-diastolic counts to the mean counts of the time-activity curve. In similar fashion, the end-systolic volume is the mean tomographic LV volume times the ratio of the end-systolic counts to the mean counts. The tomographic determination of both the end-diastolic and end-systolic volumes, including the smoothing and tomographic reconstruction, required the observer to be seated at the computer console for 11 minutes. Processing of the entire study was completed within 30 minutes.

Left ventricular cineangiography: Single-plane LV cineangiography was performed in the 30° right anterior oblique view using a pigtail catheter positioned in the body

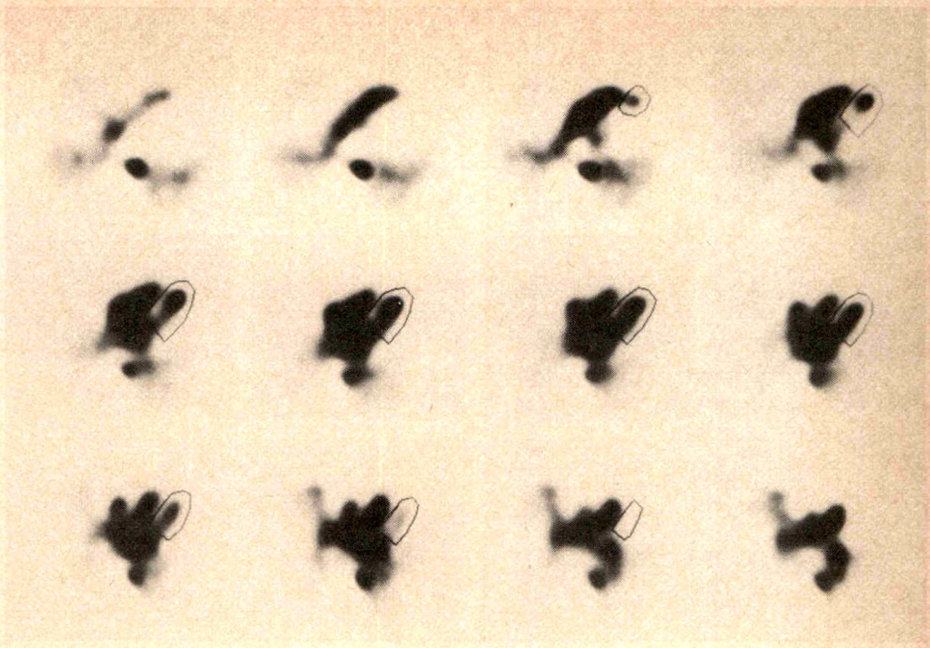

FIGURE 1. Left ventricular regions of interest for each slice. Precise localization of the endocardial surface is unnecessary.

of the left ventricle and filmed at 60 frames/s. Left ventriculograms were analyzed by a third observer by manually digitizing the end-diastolic and end-systolic frames using a VAX 750 computer according to the method of Dodge et al[1] and regression equation of Kennedy et al.[29]

For each patient in whom a technically adequate cineangiogram was recored, each observer's emission tomographically determined end-diastolic and end-systolic volumes were compared with those determined by LV cineangiography and with each other and subjected to statistical analysis by linear regression.

Results

Figure 2 is a plot of the calculated volumes of the simulated LV chamber in air vs directly measured volumes. Figure 3 is a plot of the calculated volumes of the simulated LV chamber in the torso phantom filled with water vs directly measured volumes. The addition of scattering material did not affect the accuracy of volume measurement significantly.

Figure 4 is a plot of the calculated volumes of the simulated LV chamber in the torso phantom filled with water with 10% background activity by volume vs directly measured volumes. The contribution by background counts did not affect the accuracy of volume measurement significantly. Figure 5 is a plot of calculated volumes of the simulated LV chamber in the torso phantom filled with water with 10% background activity and the addition of a simulated right ventricle vs directly measured volume. Neither scatter nor the contribution by right ventricular or background counts

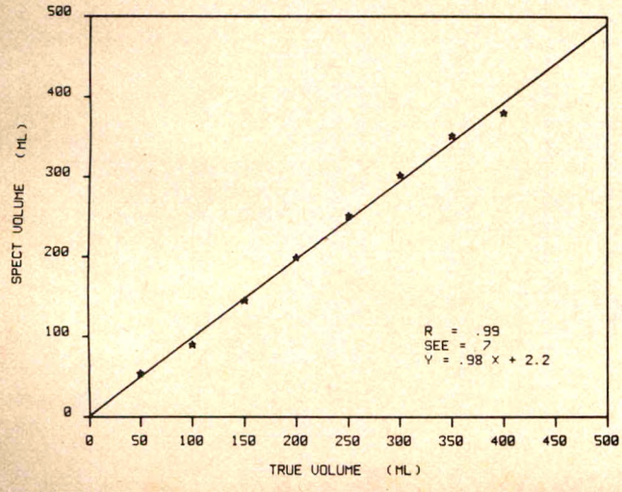

FIGURE 2. Volumes of the simulated left ventricular chamber in air determined using the count-based method compared with directly measured volumes. SPECT = single-photon emission computed tomography.

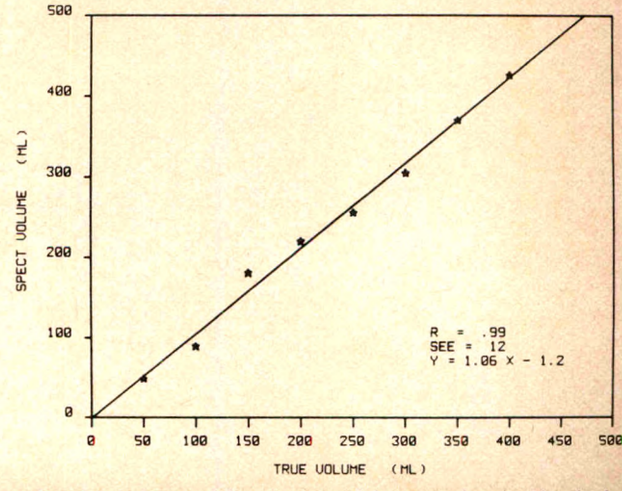

FIGURE 3. Volumes of the simulated left ventricular chamber in the torso phantom filled with water determined using the count-based method compared with directly measured volumes. SPECT = single-photon emission computed tomography.

decreased the accuracy of the measurement of simulated LV chamber volumes.

Figure 6 is a plot of LV end-diastolic and end-systolic volumes for the 30 patients with technically adequate LV cineangiograms, calculated by the first observer using the count-based emission tomographic approach vs those determined by an independent observer using cineangiography. Figure 7 is a plot of the LV end-diastolic and end-systolic volumes calculated by the first observer using the count-based emission tomographic approach against a second independent determination by the same observer. The mean deviation was 12 ml yielding good intraobserver reproducibility.

Figure 8 is a plot of LV end-diastolic and end-systolic volumes calculated by a second independent observer using the count-based emission tomographic approach against those determined by the first observer. The mean deviation was 14 ml, yielding good interobserver reproducibility.

Discussion

LV volume is an important variable in the assessment of cardiovascular physiology and pathophysiology.[30–33] The historic standard for the measurement of LV volume has been the biplane area-length method of Dodge et al.[1]

Most adult catheterization laboratories perform single-plane left ventriculography in the 30° right anterior oblique projection, after which LV volumes are calculated by the area-length method. The studies of Kennedy et al[29] and Wynne et al[34] showed that the calculated volumes are consistently larger than the biplane volumes by as much as 20%, necessitating the use of regression equations to improve their accuracy. Kennedy, using the regression equation $y = 0.81x + 1.9$ ml, compared the resulting single-plane 30° right anterior oblique volumes with those obtained from simultaneous biplane studies. He found a correlation coefficient of 0.97 and a standard error of the estimate of 22 ml for end-diastolic volume, a correlation coefficient of 0.96 and a standard error of the estimate of 17 ml for end-systolic volume, and a correlation coefficient of 0.97 with a standard error of the estimate at 24 ml for end-diastolic and end-systolic volumes combined.

Hillis et al[35] found in a large series of patients that LV volumes can be measured accurately with single-plane angiography in a 30° right anterior oblique projection using the area-length method of Dodge et al[1] and the regression equation of Kennedy et al[29] in patients with normal as well as depressed global LV function. However, single-plane LV volumes cannot be measured reliably in patients with marked segmental wall motion abnormalities, because the geometric assumptions on which the area-length method is based are probably no longer valid.[35]

Dodge et al[36] investigated the intraobserver and interobserver variability of the area-length method using

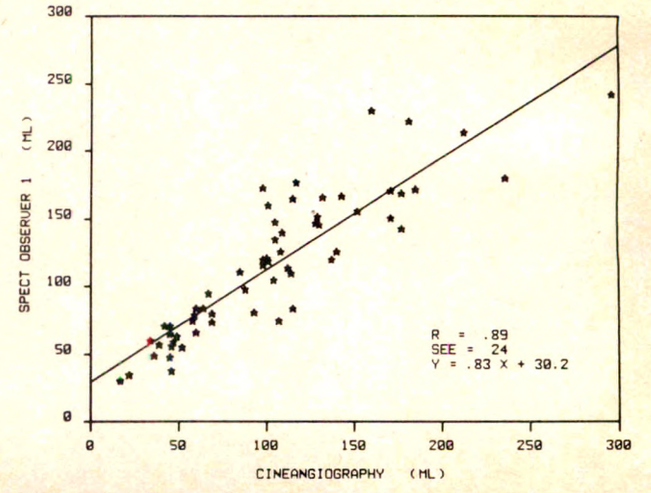

FIGURE 6. Left ventricular end-diastolic and end-systolic volumes compared with those measured by cineangiography. SPECT = single-photon emission computed tomography.

single-plane 30° right anterior oblique cineangiograms and the Kennedy regression equation. They found an intraobserver variability of 3.3 ± 3.4 ml (2.2% ± 2.0%) for end-diastolic volume and 3.2 ± 2.7 ml (5.8% ± 4.1%) for end-systolic volume, with interobserver variability of 6.6 ± 4.9 ml (4.3% ± 3.7%) for end-diastolic volume and 5.9 ± 5.3 ml (10.3% ± 10.8%) for end-systolic volume.

In considering the accuracy of SPECT end-diastolic and end-systolic volumes, it must be recognized that the comparison is being made to a single determination of the volume measured by cineangiography using a single heartbeat. Because emission tomographic volumes are derived from a mean volume acquired from approximately 1,500 cardiac cycles and the time-activity curve is derived from approximately 500 cardiac cycles, the volumes represent the mean end-diastolic and end-systolic volume during the acquisition period.

The tomographic end-diastolic and end-systolic volumes may be different from the volumes measured during the single angiographic beat, because the papillary muscles may influence volume estimates derived from analysis of the silhouette of the left ventricle, which would be more pronounced at end-systole. Patients may not be in a baseline state during the angiographic procedure. Sedatives, which may alter the patients' physiologic state, are routinely used during cardiac catheterization. Since coronary arteriography was performed before left ventriculography, the hyperosmolar contrast agent may have caused a mild increase in the blood volume, raising preload before left ventriculography. Intraventricular injection of the contrast agent begins to produce hemodynamic changes after approximately the sixth beat after injection, causing an increase in LV volume.[37] LV segmental wall motion abnormalities may have led to inaccurate cineangiographic values for end-diastolic and end-systolic volume.[35]

When comparison is made with LV cineangiography, the standard errors suggest that this emission tomographic count-based approach for the measurement of LV volume is relatively accurate and highly reproducible. The method is simple to perform and affords markedly improved counting statistics and shorter acquisition times than techniques using gated acquisition. The serious problems associated with assumptions regarding LV geometry, which may lead to inaccurate cineangiographic values for end-diastolic and end-systolic volume, are obviated.

This approach is conceptually similar to the planar count based methods, first reported by Slutsky et al.[18] The essence of the planar count-based method is that the LV count, determined from a left anterior oblique gated blood pool study, divided by the count per millilter of peripheral blood, should yield the volume of the left ventricle. The difficulties associated with this approach are that background subtraction and attenuation correction are necessary. In addition, counting efficiency correction must be done because often the blood sample is counted with different efficiency than the left ventricle.

Attenuation correction appears to be the major problem. Several approaches have been attempted using internal standards, such as an esophageal source,[20] the transverse aorta,[21] and a bolus in the right atrium,[22] or by measuring the distance from the center of the left ventricle to the chest wall.[23,24] Each group of investigators can show that their technique is reasonably accurate, but their approaches are not widely used.

The count-based SPECT approach is simple enough that any nuclear medicine laboratory using SPECT should be able to implement the technique. Its major advantages over the planar methods are that attenuation correction and background subtraction are unnecessary. The count per milliliter of blood is determined from blood in the center of the LV, so it has the same attenuation, on the average, and is counted with the same efficiency as the rest of the left ventricle. Background correction is unnecessary because there are no overlapping structures.

The only significant problem that remains is identification of the edge of the left ventricle, particularly the

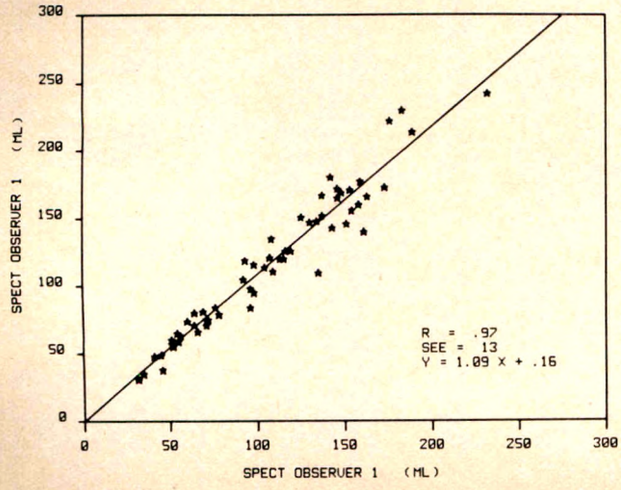

FIGURE 7. Comparison of separate determinations of left ventricular end-diastolic and end-systolic volumes by the same observer. SPECT = single-photon emission computed tomography.

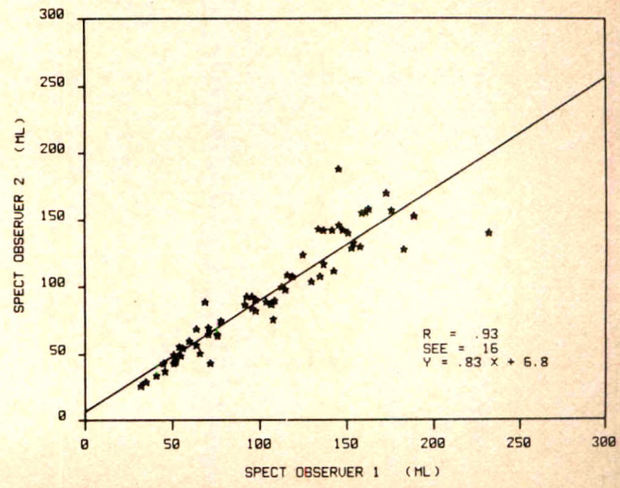

FIGURE 8. Comparison of determinations of left ventricular end-diastolic and end-systolic volumes by 2 observers. SPECT = single-photon emission computed tomography.

location of the mitral valve plane. Although it would probably be easier to identify the mitral valve plane using gated tomographic acquisition, we decided that the greater number of counts available in an ungated study would provide superior images, which should offset the advantages of the gated study. Our results are similar to those of Bunker et al,[38] who recently reported a similar technique using gated SPECT.

This emission tomographic method for LV volume measurement should apply equally well to the measurement of right ventricular volume and deserves further study. It may be possible to determine biventricular emission tomographic stroke volumes, which would allow quantitation of left-to-right shunt flow and valvular regurgitant flow.

We conclude that use of SPECT for measurement of LV volume is simple, accurate and reproducible and may be useful for diagnosis and management of cardiovascular disease.

Echocardiographic Detection of Complete and Partial Papillary Muscle Rupture During Acute Myocardial Infarction

PATRICIA C. COME, MD
MARILYN F. RILEY, BS
RONALD WEINTRAUB, MD
JAMES P. MORGAN, MD, PhD
SHOICHIRO NAKAO, MD

Papillary muscle rupture produces severe mitral regurgitation, which is generally rapidly fatal. Because echocardiography can visualize the papillary muscles and mitral leaflets, it may detect papillary muscle rupture, prompting aggressive medical and surgical therapy. In 4 patients presenting to our hospital in 1983 and 1984, emergency echocardiography was instrumental in diagnosing either complete or partial papillary muscle rupture. Characteristics of the patient population are listed in Table I and pertinent echocardiographic features are illustrated in Figures 1 to 6.

In our 4 patients, echocardiography played a pivotal role in diagnosis and therapy. In the first patient, with complete papillary muscle rupture, there was no audible precordial murmur, and the initial pulmonary artery wedge pressure tracing inexplicably failed to reveal large "v" waves. In the second patient, mitral regurgitation was audible, but the patient improved markedly with vasodilator therapy. Emergency surgery was performed because of the echocardiographic diagnosis of partial papillary muscle rupture. Severe mitral regurgitation had not been suspected before echocardiography in the third patient with partial rupture. In the fourth patient, the presence of a mechanical defect in the setting of preserved septal and anterior wall motion prompted surgery.

Our 4 patients illustrate the spectrum of echocardiographic abnormalities that may be found in patients with complete or partial papillary muscle rupture. Complete papillary muscle rupture may be characterized by 1 or more 2-dimensional findings: abnormal cut-off of 1 papillary muscle; a mobile mass attached to chordae and to the mitral valve, which could simulate a valvular tumor, thrombus or vegetation; and a pattern of mitral prolapse or of a flail mitral leaflet.[1–4] Partial papillary muscle rupture has been reported only once previously. Nishimura et al[5] described an echocardio-

In diastole, transection of 1 of the papillary muscles (PM) is seen. During systole, the PM is seen to flail into the left atrium (LA) (**right**). ANT MV = anterior mitral valve leaflet; AoV = aortic valve; LV = left ventricle; SG = Swan Ganz catheter in the right side of the heart.

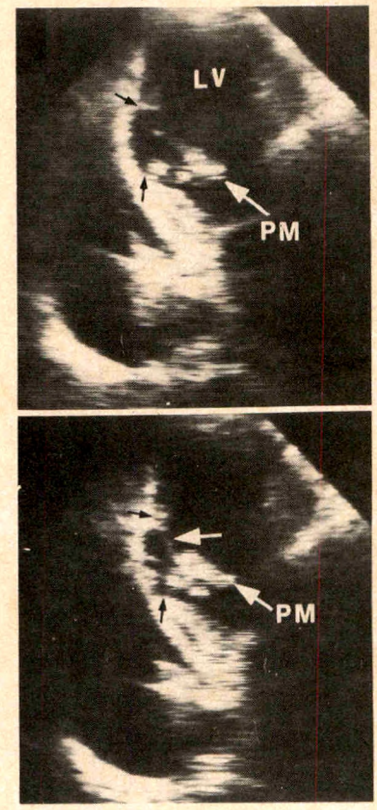

FIGURE 2. Apical views of the left ventricle (LV) obtained with slight changes in transducer angulation, from the second patient, in whom partial rupture of the posterior papillary muscle (PM) was confirmed at surgery. There is marked thinning of a localized portion of the inferoposterior wall (area between the 2 unlabeled **black arrows**). This region of myocardium was akinetic on the 2-dimensional scan. **Top,** no definite connection can be seen between the inferoposterior wall and the papillary muscle. With a slight change in transducer angulation, **(bottom),** however, a thread-like connection (**white arrow**) is evident, attaching the papillary muscle to the distal portion of the thinned myocardial region. There was increased echo-reflectivity from the papillary muscles, suggesting fibrosis.

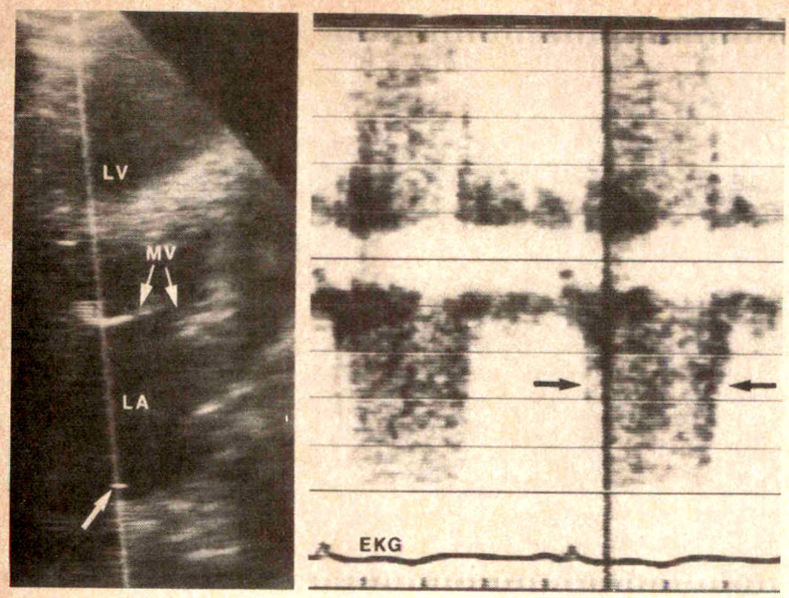

FIGURE 3. Apical 2-dimensional echocardiogram (**left**) and Doppler echocardiographic recording (**right**) from the second patient reveals holosystolic turbulence (**between 2 black arrows**) with sample volume placement (**unlabeled white arrow**) at the back wall of the left atrium (LA). EKG = electrocardiogram; LV = left ventricle; MV = mitral valve.

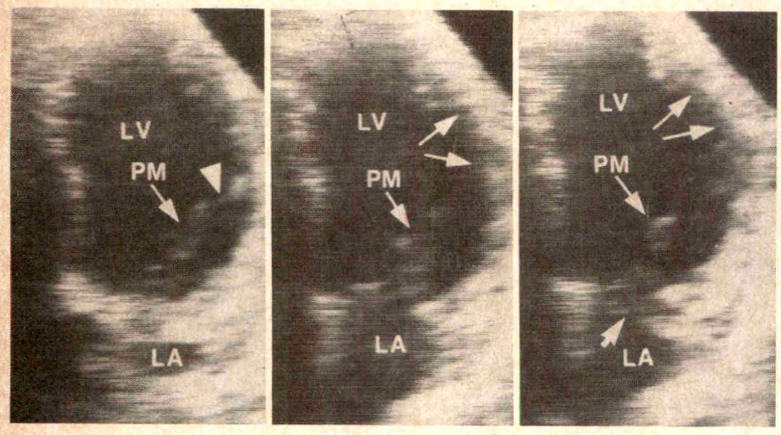

FIGURE 4. Apical views of the left ventricle (LV) in the third patient, with partial rupture of the posteromedial papillary muscle. **Left,** a tenuous attachment of the papillary muscle (PM) to the posterior wall is evident (**arrowhead**). **Middle** and **right,** dropout of myocardial echoes in the regions where PM attachment would be expected (**longer arrows**) and eliminate systolic protrusion of part of the PM into and through (**short arrow**) the mitral valve. LA = left artium.

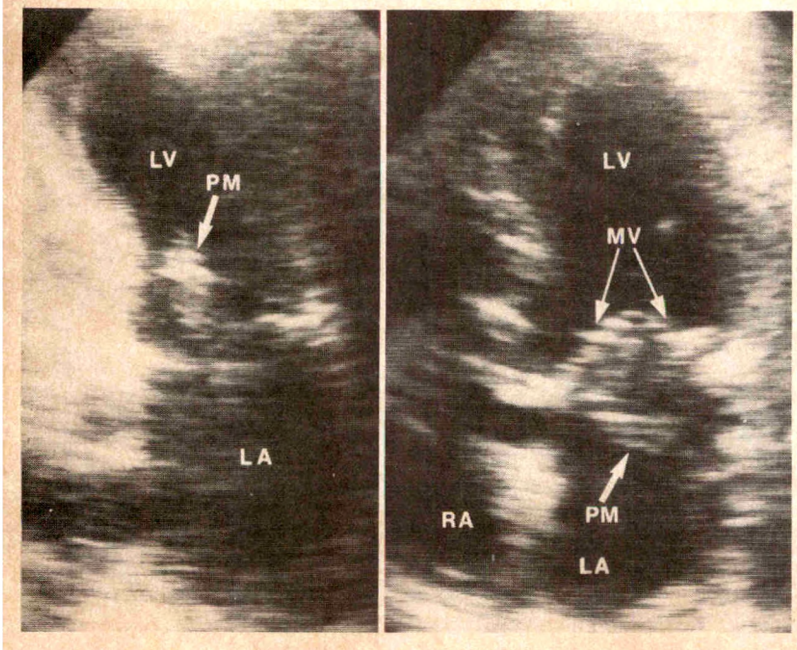

FIGURE 5. Apical views of the left ventricle (LV) in the fourth patient, with complete papillary muscle (PM) rupture. In diastole (**left**), the PM was seen to fling freely within the LV. In systole (**right**), the PM was thrust into the left atrium (LA). The flail motion of the anterior mitral valve (MV) leaflet is not evident in this view. RA = right atrium.

TABLE I Characteristics of the Patients

Pt	Age (yr) & Sex	Location AMI	Interval (days) from Onset of AMI to Clinical Deterioration	APE	SAP (s/d) (mm Hg)	Precordial Murmur	Mean PAWP (mm Hg)	CO (l/min)	MVR	Died	PM Rupture	
											Partial	Complete

4	84M	Inferior	7	+	40/-	+(3/6)	*28	*4.2	+	+	0	+

* Measurements performed after institution of intraaortic balloon counterpulsation.
AMI = acute myocardial infarction; APE = acute pulmonary edema; CO = cardiac output; MVR = mitral valve replacement; PAWP = pulmonary artery wedge pressure; PM = papillary muscle; SAP (s/d) = systemic arterial pressure (systolic/diastolic).

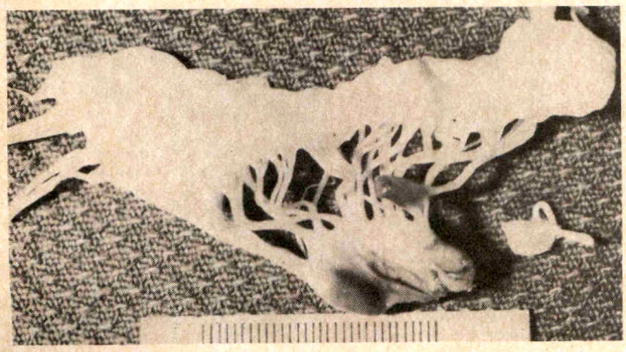

FIGURE 6. Operative specimen from the fourth patient illustrates the necrotic, jagged edge of the completely ruptured papillary muscle.

graphic pattern suggestive of disruption of part of the posteromedial papillary muscle in a patient whose condition subsequently deteriorated further; the patient was found to have complete papillary muscle rupture at unsuccessful mitral valve replacement.[5] Their report suggested that partial muscle rupture might be recognizable before complete rupture. By facilitating recognition of complete or partial papillary muscle rupture, echocardiography may prompt earlier surgical intervention.

Sequential Balloon Technique in Angioplasty of Severe Coronary Arterial Obstructions

PETER GANZ, MD

Experienced angiographers have noted that attempts at percutaneous transluminal coronary angioplasty (PTCA) for stenoses of greater than 90% luminal diameter are associated with higher rates of both technical failure and complications.[1] Technical failure usually results from inability to pass the balloon catheter through a tiny and irregular residual channel, even though the guide wire had crossed previously. The best chance of passing through such lesions is to use a balloon that, in the deflated state, presents the smallest possible impaction surface (a "low profile") to the stenosis as it is advanced over the guide wire. On the other hand, the best chance of achieving both primary and long-term patency in PTCA is through use of a relatively large (higher profile) balloon which, when fully inflated, slightly exceeds the diameter of nearby normal segments of the artery.[2,3] We describe the clinical results of a sequential balloon technique that accomplishes both of these conflicting goals in the same procedure.

PTCA was applied in 74 severely narrowed or totally occluded vessels (45 left anterior descending (LAD) arteries, 14 circumflex arteries, 10 right coronary arteries, 4 coronary bypass grafts and 1 left main coronary artery) after initial successful passage of the guide wire through the obstruction. In most cases, these guide wires were either very flexible, straight-tipped, 300-cm exchange wires (Advanced Cardiovascular Systems—ACS) or steerable wires with slightly curved tips (USCI). A 2.0-mm ACS balloon catheter was then passed over the wire through the lesion. Once the balloon was in proper position, 2 to 4 inflations were carried out at 120

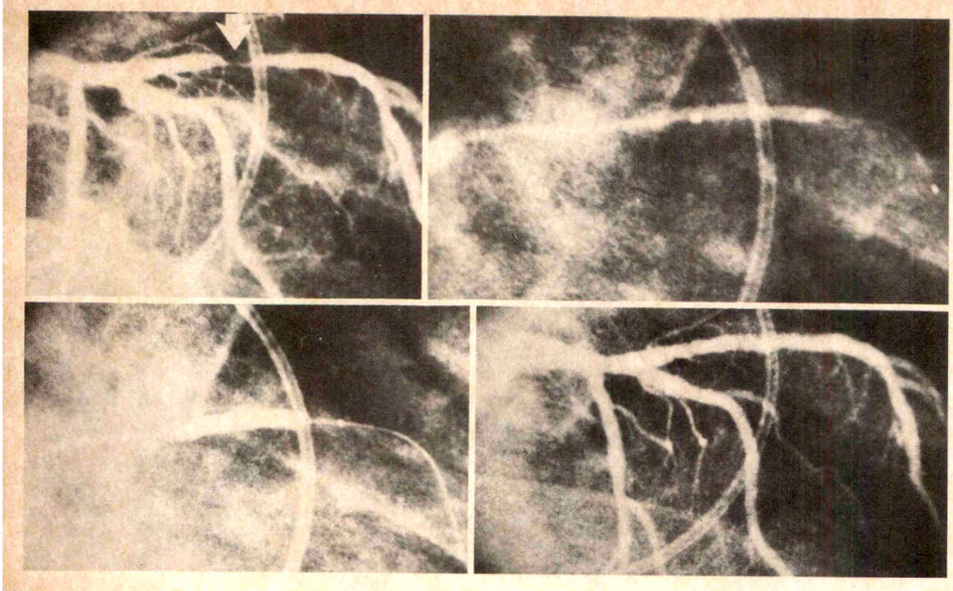

FIGURE 1. Right anterior oblique projections of left coronary arteriogram before, during and after percutaneous transluminal coronary angioplasty (PTCA) of the left anterior descending coronary artery. **A,** before PTCA there is severe stenosis of the proximal left anterior descending coronary artery (**arrow**). **B,** inflation of a 2.0-mm balloon. **C,** subsequent inflation of a 3.5-mm balloon after exchange over the guide wire. **D,** after PTCA, there is complete relief of the obstruction.

to 130 psi, each lasting approximately 45 seconds. If the steerable guide wire had been used initially, it was then removed and the 300-cm exchange wire was inserted through the balloon catheter (the tip of which was already beyond the stenosis) out into the distal segment of the vessel. The balloon was then retracted back into the guiding catheter, leaving the guide wire still positioned across the stenosis. A single contrast injection was obtained to check vessel patency. With the wire position carefully maintained under fluoroscopic control, the 2.0-mm balloon catheter was removed from the guiding catheter and a 3.0 or 3.5 mm ACS balloon catheter (depending on the size of the vessel) was inserted over the wire in its place. When this balloon was properly positioned, it also was inflated 2 to 4 times at 120 to 130 psi for 45 seconds each. The procedure was considered successful if the percent diameter stenosis was reduced by at least 20% and the residual stenosis at the end of the procedure did not exceed 60%.

Among the 74 vessels in which the sequential balloon technique was used, primary success was achieved in 65 (88%). These 65 successful PTCAs resulted in reduction of mean diameter stenosis from 92% to 28%. Of the 65 obstructions, 55 were initially at least 90% narrowed. Figure 1 is an example of application of the sequential balloon technique in PTCA of a severe LAD stenosis. Figure 2 shows its use in total occlusion of the distal right coronary artery. Among the 9 technical failures, 5 were a result of inability to cross the lesion with a 2.0-mm balloon after it had been satisfactorily crossed with a guide wire. In 1 additional failure, the lesion was initially dilated with a 2.0 mm balloon, but subsequently we could not cross it using a 3.5 mm balloon. In the last 3 cases, the lesions were crossed and dilated with both small and large balloons, but thrombi developed in the coronary arteries at the site of PTCA during the procedure.

Significant complications occurred in 4 cases (5%). The first 3 were the aforementioned thrombotic episodes during the procedure. Two of these 3 patients underwent successful emergency coronary bypass surgery (among the entire group, therefore, emergency bypass surgery was needed in 3%); the third had a small and uncomplicated anterior wall acute myocardial infarction. The fourth complication resulted from acute thrombosis of the LAD 5 days after initially successful PTCA. This patient was returned to the catheterization laboratory and underwent successful thrombolysis with intracoronary streptokinase.

The usefulness of the sequential balloon technique was suggested early in our PTCA experience. In several cases in which we wished to use 3.0- or 3.5-mm balloons to achieve complete dilatation, we could not initially pass these larger balloons over the guide wire through severe stenoses. In each instance, switching to a smaller, lower profile balloon resulted in successful passage. Creation of a track by first dilating with the small balloon then allowed subsequent introduction of the larger balloon without difficulty. The recent policy in our laboratory has been to routinely use the small balloons first in all patients with severe coronary obstructions, without even trying to initially pass the larger balloons.

Our experience shows that once a severe obstruction has been crossed with the guide wire, a 2.0-mm balloon can usually be passed (69 of 74 cases, 93%). When this small balloon is inflated initially to create a track, a larger balloon can almost always be passed across the lesion (68 of 69 cases, 99%). Thus, 2 goals are accomplished: initial crossing of the obstruction in a manner that is least traumatic and most likely to be successful, and subsequent use of a large balloon to create a wide residual lumen. Recent studies have emphasized the importance of the latter goal. Duprat et al[2] showed that residual stenoses after PTCA were minimized when the ratio of inflated balloon diameter to coronary arterial diameter was 1.1 to 1.3. Schmitz et al[3] performed follow-up coronary angiography in 86 patients a mean of 5.6 months after PTCA and found that in cases in which the balloon size had been smaller than the prestenotic vessel lumen, restenosis occurred in 36%, whereas it occurred in only 5% of cases in which the balloon size had exceeded the prestenotic vessel lumen.

This technique has several disadvantages. Procedure time is lengthened and intracoronary manipulation is

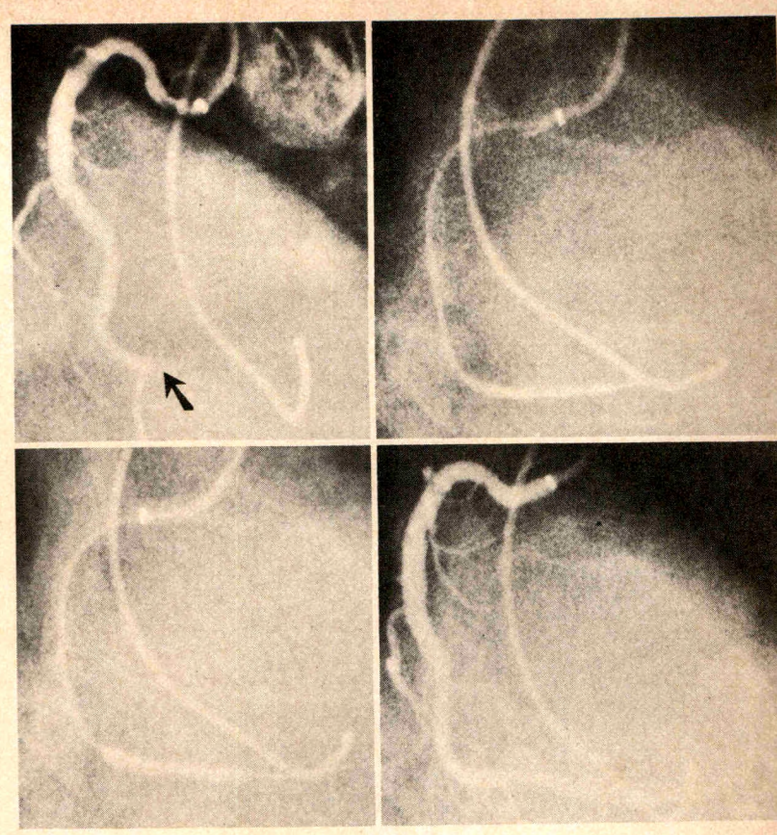

FIGURE 2. Left anterior oblique projections of right coronary arteriogram before, during and after percutaneous transluminal coronary angioplasty (PTCA) for complete obstruction of the distal right coronary artery (RCA). **A,** complete obstruction of the distal RCA (**arrow**) proximal to the origins of the posterior descending and the posterior left ventricular branches. **B,** after crossing the obstruction with a guide wire, a 2.0-mm balloon catheter was inserted and the balloon inflated. **C,** subsequent inflation of a 3.0-mm balloon, after catheter exchange over the guide wire. **D,** after PTCA, the obstruction has been almost completely relieved and normal anterograde flow restored to this strongly dominant RCA.

increased. Occasionally, displacement of the guide wire out of the coronary artery may inadvertently occur during balloon catheter exchange. Finally, the cost of the procedure is greater, because 2 balloon catheters are needed, and each costs $350 or more.

An early report by Cowley et al[4] in 1981 suggested that results of PTCA in vessels with stenoses of at least 90% are considerably worse than in less severely narrowed vessels. Our results, achieved with more modern equipment and techniques, show that even when severe narrowing or total occlusion is present, if a guide wire can be passed through the lesion, the likelihood of success approaches 90% and the incidence of complications is low. The sequential balloon technique appears to offer the best chance of traversing very severe obstructions and creating the widest possible residual lumen by 2 graded dilatations.

Surgical Treatment of Medically Refractory Variant Angina Pectoris: Segmental Coronary Resection with Aortocoronary Bypass and Plexectomy

CHRISTOPHER DiPAOLO, MD
NICHOLAS Z. KERIN, MD
MELVYN RUBENFIRE, MD
FREDERICK LEVINE, MD

Prinzmetal, in 1959, described the syndrome of variant angina pectoris (VAP). He hypothesized that episodes of ischemia were the result of a superimposed "normal increase in the tonus of the vessel wall."[1] The treatment of VAP consists of calcium channel blocking agents and nitrates. Although nitroglycerin is highly effective in the acute setting, the response to long-term nitrate administration is less satisfactory. Antman et al[2] reported that among patients in whom conventional therapy with nitrates and β-blocking agents fails, 87% had at least 50% reduction in anginal frequency with nifedipine. However, some patients are refractory to medical therapy. A variety of surgical procedures have been reported; their relative benefits remain controversial, and theoretical objections have been raised. In this report, we describe a patient with medically refractory coronary vasospasm who underwent a unique surgical procedure.

A 60-year old man was admitted in May 1980 for investigation of VAP. During hospitalization, the frequency of angina at rest increased to daily occurrences. Cardiac catheterization revealed a normal dominant right coronary artery. The circumflex artery was large and narrowed by 20% of its diameter distal to the take-off of a first lateral branch (Fig. 1A). After 3 doses of ergonovine, 0.05 mg intravenously at 2-minute intervals, the coronary arteries were again visualized. An 80% diameter narrowing in the proximal circumflex artery was induced (Fig. 1B), accompanied by severe chest pain and ST elevation in inferior leads. Although medical treatment was administered (Fig. 2) the pain persisted. In August, he was hospitalized with angina (up to 10 episodes/day). Holter monitoring revealed symptomatic episodes of 2:1 atrioventricular block with a ventricular rate as low as 30 beats/min requiring a VVI transvenous pacemaker. In April 1982, still disabled by resting angina, he was readmitted and underwent cardiac catheterization during which he had spontaneous angina and ST elevation. An injection into the left coronary artery revealed complete occlusion of the circumflex artery (Fig. 3A). The right coronary artery was normal. After injection of 5 mg of phentolamine into the left coronary artery, the artery became patent (Fig. 3B).

On April 17, 1982, a 2-cm resection of the spastic segment with ligation of the upper segment and saphenous vein bypass to the distal posterior circumflex artery and plexectomy were performed. No further episodes of angina occurred until January 1985. Cardiac catheterization was performed again in August 1984. The point of excision of the circumflex artery was seen (Fig. 3C). The graft to the distal circumflex was patent (Fig. 3D). A total of 0.8 mg of ergonovine was injected and resulted in no abnormal response.

Review of previous reports indicates that coronary artery bypass grafting (CABG) may be performed with an outcome comparable to that obtained with classic angina pectoris[3] in patients with VAP and significant fixed coronary stenosis. The addition of plexectomy may reduce the frequency of recurrent angina without increased operative risk.[4] Our patient, with VAP and close to normal coronary arteriographic findings, was intractable to medical treatment, including nitrates, nifedipine, verapamil, diltiazem and amiodarone. Angina persisted at a rate of about 10 episodes/day. Angiographically, the spontaneous coronary vasospasm was localized in a proximal nondominant circumflex artery at the site of early atherosclerotic changes. The segment of the circumflex artery displayed excessive vasoconstrictor activity, both spontaneously and in response to ergonovine (Fig. 1B and 2A). Regardless of whether the primary pathogenic mechanism is α-adrenergic or on the basis of local vasoconstriction supersensitivity (triggering zone), resection of the involved arterial segment plus plexectomy resulted in cessation of spontaneous angina and ergonovine inducible vasospasm. A similar approach was probably used by Heupler et al,[5] who reported three patients who underwent resection of the right coronary artery with

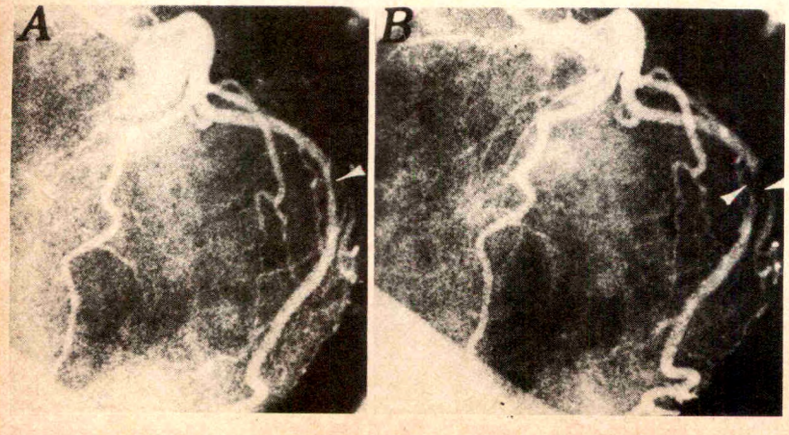

FIGURE 1. A, the left coronary artery had trifurcated into the left anterior descending, intermediate and circumflex branches. The circumflex artery had a 20% narrowing (**white arrow**). **B,** upon ergonovine challenge, an 80% focal spasm in the proximal circumflex artery was induced (**arrows**).

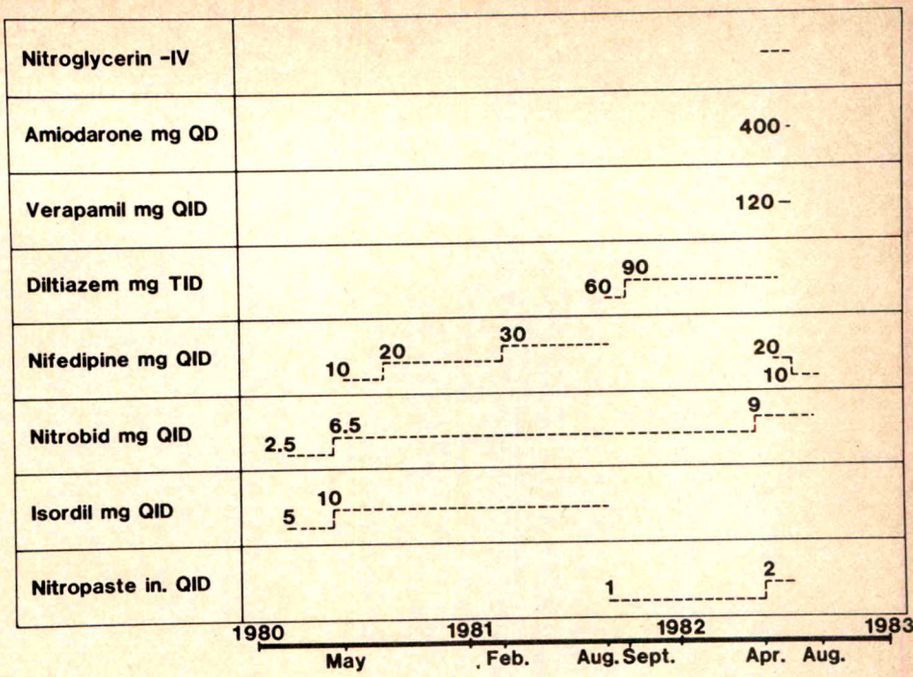

FIGURE 2. Pharmacologic interventions.

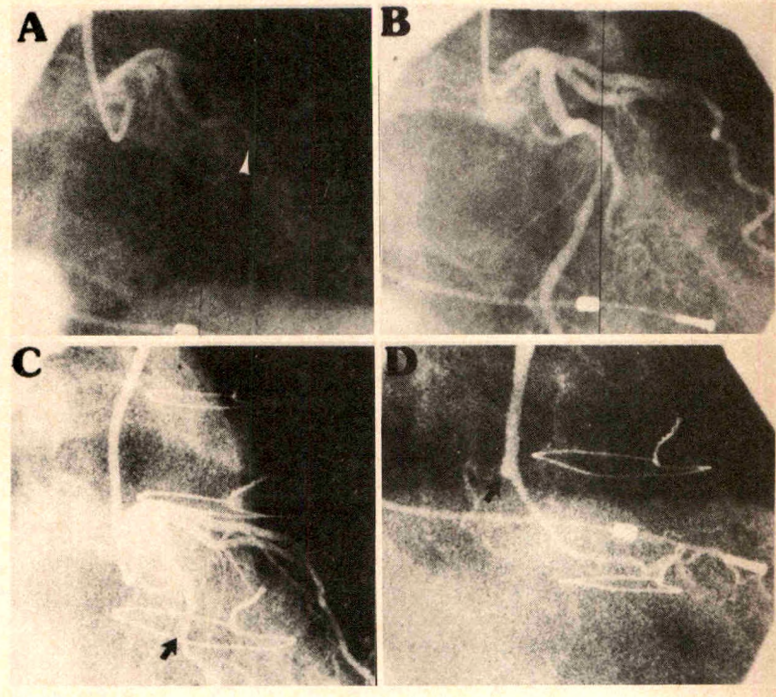

FIGURE 3. A, during repeat coronary angiography, spontaneous spasm with complete occlusion of the circumflex artery occurred in the region where ergonovine previously had induced spasm. **B,** after intracoronary administration of phentolamine, spasm disappeared. The patient underwent segmental resection of the circumflex artery in the area of angiographic spasm with vein bypass to the distal segment and plexectomy. **C,** Postoperatively, injection into the native left coronary artery shows a proximal stump occlusion (**arrow**) at the site of segmental resection of the circumflex artery. **D,** injection into the graft showed a patent distal circumflex artery.

CABG. Their detailed surgical and clinical courses were not provided.

Considering the variability of the course of VAP and the fact that spontaneous coronary spasm may be unpredictable, involving long segments of multiple vessels, this surgical approach might not be applicable to those patients without documentation of spontaneous or ergonovine-induced focal coronary vasospasm. We recommend combined coronary resection, CABG and plexectomy for patients with medically refractory VAP and focal coronary spasm. Randomized trials are unlikely, given the rarity of this entity.

Relation of Acute Myocardial Infarction to Cocaine Abuse

LOUIS L. CREGLER, MD
HERBERT MARK, MD

It is estimated that 10 million Americans have used cocaine and that 5 million use it regularly.[1] Although cocaine was first introduced in 1884 as a local anesthetic, little information appeared on the cardiovascular effects of cocaine use until recently. Cocaine abuse has been associated with tachycardia, systemic hypertension, ventricular arrhythmias, acute myocardial infarction (AMI) and sudden death.[2–7] Coleman et al[2] reported the first case of AMI associated with illicit use of cocaine; however, the patient was presumed to have underlying coronary artery disease, although he did not undergo coronary angiography. Kossowsky and Lyon[3] described 6 patients with AMI attributed to cocaine abuse. Four of their patients had some degree of atherosclerotic narrowing of the coronary arteries by angiography or autopsy and 2 did not have cardiac catheterization. Schachne et al[4] described another patient whose coronary arteries were normal. We describe another cocaine user who had AMI.

A 38-year-old white man had been well until age 32 years (April 1979), when he had a documented inferior wall AMI. After an uncomplicated course, he was transferred to the Bronx Veterans Administration Medical Center 3 weeks later. Blood pressure on admission was 120/80 mm Hg and serum cholesterol was normal. Cardiac catheterization and selective coronary angiography with left ventriculography was performed. The coronary arteries and the left ventricle were normal. Provocative maneuvers did not produce spasm. After discharge, he was asymptomatic but continued to use cocaine and heroin sporadically. Before AMI, he had increased his cocaine use to 3 times per week. He was readmitted to the coronary care unit 6 months later (November 1979) with an extensive anterior lateral wall AMI. Chest pain occurred 45 minutes after intranasal administration of cocaine. Selective coronary angiography again showed normal coronary arteries. The left ventricular ejection fraction was 68%. The infarctions were believed to have been induced by coronary artery spasm, but this could not be demonstrated by repeat ergonovine administration. He has been followed up by the cardiology service for the past 6 years. He has not used drugs for the past 5 years, although he continues to smoke cigarettes heavily and is a heavy alcohol binge drinker. He has not had chest pain or other cardiovascular symptoms since his last AMI. His blood pressure is 130/80 mm Hg. Left ventricular function by gated blood pool scintigraphy in August 1984 showed an ejection fraction of 53%.

Our patient is similar to the case reported by Schachne et al.[4] He also shares a common feature with several of the patients described by Kossowsky and Lyon[3] in that he was a mixed-substance abuser. Cocaine is a potent vasoconstrictor. It constricts blood vessels and prevents its own absorption.[5] AMI in any young patient who does not have risk factors should raise the suspicion of the possibility of coronary spasm related to recreational cocaine use. The prognosis for a patient who survives the initial infarction and has good left ventricular function appears to be excellent if cocaine usage is discontinued.

Acknowledgment: We gratefully acknowledge the excellent secretarial services rendered by Bernice McKay.

Coronary Arterial Findings After Accidental Death Immediately After Successful Percutaneous Transluminal Coronary Angioplasty

ALAN L. SOWARD, FRACP
CATHERINA E. ESSED, MD
PATRICK W. SERRUYS, MD

From the Cardiac Catheterization Laboratory and Department of Pathology, Thoraxcenter, Erasmus University, P.O. Box 1783, 3000 DR Rotterdam, The Netherlands. Manuscript received February 27, 1985; revised manuscript received April 29, 1985, accepted April 30, 1985.

The mechanism by which percutaneous transluminal coronary angioplasty (PTCA) achieves its results remains minimally documented. Plaque compression and redistribution was the initial postulate for the success of arterial dilatation in peripheral atherosclerotic disease. Subsequent animal and human cadaver experiments[1] and human postmortem examinations[2,3] suggest plaque splitting and disruption with stretching of the nonatherosclerotic arterial wall. We present the pathologic findings in a patient who died immediately after a technically successful PTCA after an inadvertent intracoronary injection of lidocaine.

A 65-year-old woman with a 6-year history of angina pectoris was admitted with prolonged ischemic chest pain. Anteroseptal ST-segment depression was present, but no Q waves developed despite a moderate increase in cardiac en-

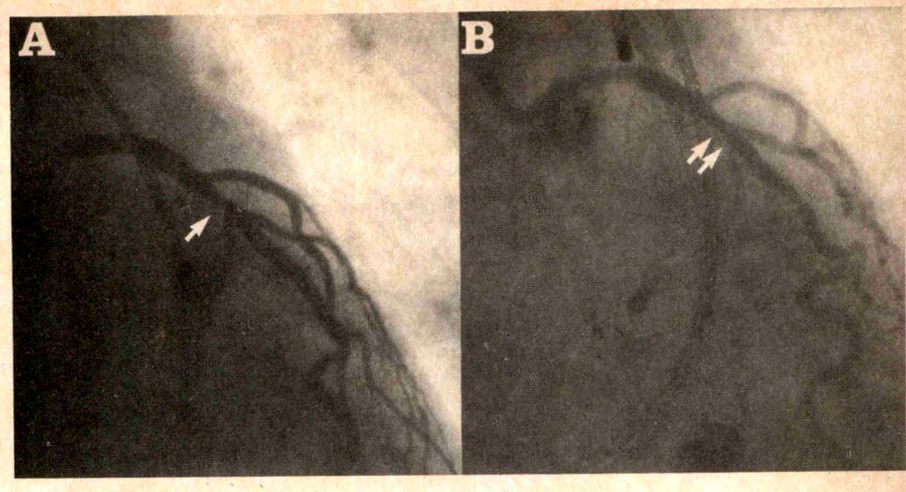

FIGURE 1. Left anterior descending coronary artery stenosis (**arrows**) (right anterior projection). **A,** before angioplasty; **B,** after angioplasty.

zyme levels. Cardiac catheterization after 10 days of continuing unstable angina revealed that the right coronary artery had an 85% narrowing of luminal diameter and the left circumflex artery was completely occluded. The left anterior descending artery (LAD) was narrowed 65% as seen in the right anterior oblique projection (Fig. 1A). The inferior left ventricular wall was moderately hypokinetic.

We decided to proceed to PTCA of the LAD and right coronary artery. PTCA of the LAD was accomplished using a 20–35 Meditech balloon and steerable guidewire system. Three dilatations to a maximal inflation pressure of 8 atm and total occlusion time of 135 seconds reduced the mean transstenotic gradient from 70 to 29 mm Hg. The postdilatation angiogram showed a reduction in diameter narrowing to 40% (Fig. 1B). In attempting a left anterior oblique view, 7 to 10 ml of a nonradiopaque fluid was injected into the left coronary artery. This had been mistaken for contrast medium and was later identified as 2% lidocaine. After 2 minutes of increased PR interval and QRS width, complete atrioventricular block developed, with no subsidiary escape rhythm. Resuscitative measures were unsuccessful.

Postmortem angiography confirmed a satisfactory angiographic result of PTCA. At autopsy an inferior infarct was found that was about the same age as the admission infarct. At the PTCA site, a split extended through the atheromatous plaque to the media with dissection and lifting of the plaque from the media (Fig. 2). A hemorrhagic area within the plaque opposite the split had an appearance that suggested that its occurrence predated PTCA.

In this patient, technically successful PTCA was achieved by splitting of the atheromatous plaque, and the patient died from an unrelated cause. Of the few previous reports of the pathologic findings in patients who died early after PTCA, plaque splitting was a frequent finding. However, most patients died from complications of acute myocardial infarction initiated by the PTCA.[2–4] Pathologic changes observed late after PTCA have been variable. An intense fibrocellular proliferation almost occluding the LAD lumen was found in 1 patient who died during repeat PTCA.[5]

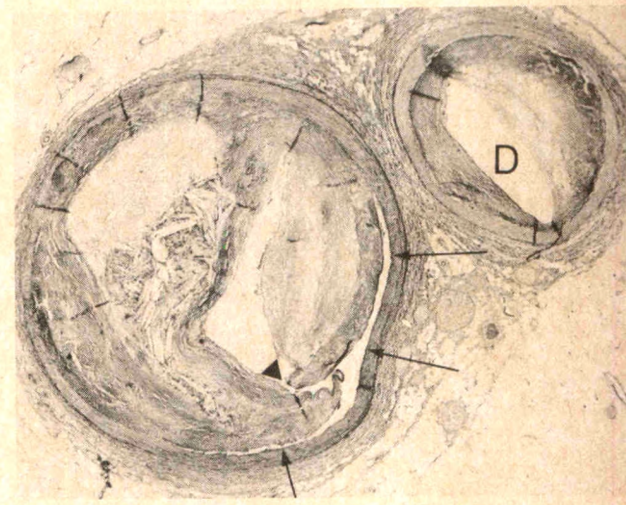

FIGURE 2. Cross section through the proximal part of the left anterior descending artery and adjacent diagonal branch (D). An atherosclerotic plaque with hemorrhage is narrowing the lumen. The plaque opposite shows disruption and splitting (**arrowhead**) and is dissected and lifted from the media (**arrows**). Apart from an atherosclerotic narrowing of the lumen, the diagonal branch does not show other changes.

Three other patients[4] showed no pathologic changes attributable to PTCA, although these were technically successful, and only 1 patient had recurrence of mild angina.

Exercise-Related Bundle Branch Block in Children

J. TIMOTHY BRICKER, MD
MALINDA S. TRAWEEK, MS
DAVID A. DANFORD, MD
THOMAS A. VARGO, MD
ARTHUR GARSON, Jr., MD

Exercise-related bundle branch block (BBB) in children is an uncommon occurrence. Most information about exercise-related BBB in children is anecdotal. We examined its frequency and significance among young persons with and without cardiac disease.

Maximal treadmill exercise testing was performed using the modified Bruce protocol[1] by 2,761 children and young adults, including 264 normal children, over a 10-year period (from July 1974 to August 1984). Electrocardiographic leads II, aVF and V_5 were continuously monitored throughout exercise with recording of a 1-lead electrocardiogram during each stage of exercise. Criteria for development of BBB were an abrupt QRS prolongation (longer than 0.12 second) during exercise and a narrow QRS at rest.

BBB developed during exercise testing in 2 girls and in 4 boys, aged 9 to 18 years (mean 11). None had a normal heart: 5 had congenital heart disease (valvular aortic stenosis (AS) in 1 patient, subvalvular AS in 2 patients, postoperative repair of primum atrial septal defect in 1, and postoperative repair of tetralogy of Fallot in 1) and 1 had cardiomyopathy (Table I). ST-segment depression (greater than 2 mm, flat or downgoing at 0.08 second) was found in 3 of the patients with exercise-induced BBB. A right BBB pattern was found in 4 patients and left BBB pattern in 2 (1 with cardiomyopathy and 1 with subaortic stenosis). Heart rate at onset ranged from 100 to 195 beats/min (mean 136). Rate at return to normal conduction ranged from 72 to 160 beats/min (mean 119). In each case, the rate at onset of BBB was higher than the rate at return to normal condition. No arrhythmias were observed during exercise testing in any patient. Physical working capacity was under the 5th percentile for age in the patient with cardiomyopathy. The patient with repaired atrial septal defect was active in sports. Each patient with valvular AS or subvalvular AS and the child with tetralogy of Fallot were normally active, but had been restricted from participation in competitive sports because of cardiac disease. The child with cardiomyopathy was limited in activity and had been restricted from sports competition. Follow-up studies ranged from 1 to 8 years (mean 4.2). No patient died during follow-up. One child required further surgery for AS. BBB during exercise was not observed in the 264 normal children.

From the Lillie Frank Abercrombie Section of Cardiology, Department of Pediatrics, Baylor College of Medicine, Houston, Texas, and the Department of Pediatric Cardiology, Texas Children's Hospital, 6621 Fannin, Houston Texas 77030. This study was supported in part by 4 grants from the National Institutes of Health, Bethesda, Maryland: General Clinic Research Branch Grant RR-00188, U.S. Public Health Service Grant HL-07190, Research Career Development Award HL-00571, and Young Investigator's Award HL-24916. Manuscript received February 1, 1985; revised manuscript received April 18, 1985, accepted April 23, 1985.

The incidence of exercise-related BBB in an adult population with heart disease is approximately 0.4 to 0.9%.[2] Our incidence of 0.2% indicates that exercise-related BBB is less frequent among children than among adults with heart-disease. This finding is consistent with the lower incidence of aberrant conduction with supraventricular tachycardia in children[3] than in adults.

BBB during exercise may be confused with ventricular tachycardia. Lack of atrioventricular dissociation and a rate similar to the narrow QRS rate at both the onset and recovery from bundle branch configuration allow this differentiation (Fig. 1 to 3).

Sandberg[4] believed that the development of BBB in an older population was related to ischemic cardiac disease, whereas exercise-related BBB in a younger population was unrelated to cardiac disease. Our observations on a young population indicate that exercise-related BBB is associated with cardiac disease.

Whereas exercise BBB is predominantly related to coronary disease among adults,[2,5] we noted an association with AS among children. The occurrence of exercise-related BBB was present in 3 of 153 of our patients with AS who underwent exercise testing. AS with rate-related BBB in adult patients was reported by Fisch et al.[2] Exercise BBB after repair of congenital cardiac disease was observed in subjects in our study; this finding has not been previously emphasized.

BBB that develops during exercise makes interpretation of ST segments difficult or impossible. Three of our patients had "ischemic" ST-segment changes before onset of BBB. Although exercise-related BBB could be related to autonomic causes[2] and may be unrelated to

TABLE I Clinical Data in Six Patients with Exercise-Related Bundle Branch Block (BBB)

Pt	Age (yr) & Sex	Diagnosis	Form of BBB	Onset HR (beats/min)	HR at Return to NL QRS (beats/min)	Peak HR (beats/min)	"Ischemic" ST Changes Before BBB	Physical Working Capacity (Percentile)
1	18M	Valvular AS	Right	190	160	205	+	>95th
2	10M	Subvalvular AS	Right	110	104	178	0	80th

Pacemaker Twiddler's Syndrome: An Important Cause of Diaphragmatic Pacing

ANIL KUMAR, MD
CHARLES R. McKAY, MD
SHAHBUDIN H. RAHIMTOOLA, MB, FRCP

Pacemaker Twiddler's syndrome (PTS) is characterized by permanent pacemaker malfunction owing to pacemaker generator manipulation by the patient. The classic syndrome, as first described by Bayliss et al,[1] consists of failure of ventricular pacing and occurrence of diaphragmatic pacing due to phrenic nerve stimulation as a result of the manipulation of the prepectoral pulse generator by the patient. In that patient, the pacemaker lead was turned around the generator in the capacious packet by a "capstan effect." This syndrome is rare; only 3 patients have been described.[1,2] The syndrome has been broadened by some to include: any significant generator manipulation,[2] or a "flipped pulse generator" due to manipulation of abdominally implanted generator,[2,3] and an attempted suicide by generator manipulation.[4] We describe a patient with PTS to reemphasize the classic syndrome with its unusual clinical presentation.

From the Section of Cardiology, Department of Medicine, University of Southern California School of Medicine, 2025 Zonal Avenue, Los Angeles, California 90033.

Manuscript received February 11, 1985; revised manuscript received April 16, 1985, accepted April 25, 1985.

A 76-year-old man had recurrent near syncope associated with atrial fibrillation with ventricular response, from 38 to 50 beats/min, 7 years after uncomplicated aortic valve replacement with the Smeloff-Cutter prosthesis. A VVI transvenous permanent pacemaker was implanted in the left pectoral region. A tined ventricular lead was introduced through the left subclavian vein; placement of the lead in the right ventricular apex was confirmed by a chest radiograph (Fig. 1), and ventricular pacing thresholds were appropriate. One week later he returned to the emergency room with a heart rate of 40 to 60 beats/min with rhythmic jerking movements of the left upper abdomen at a rate of 70 beats/min. The implantation site was well healed. An electrocardiogram showed atrial fibrillation with a slow ventricular response. The pacemaker generator pulse artifacts were also seen on the electrocardiogram at rate of 70 beats/min, but there was failure to sense or pace the ventricle. Lead perforation was suspected. The chest radiograph, however, showed that the ventricular lead was wrapped repeatedly around the pulse generator; its distal lead tip was located near the first

rib (Fig. 2). The patient denied manipulating the pulse generator but mentioned frequent itching in the left axilla, which had led him to scratch it vigorously. Using an external programmer, the pacemaker voltage amplitude was halved and the pulse width was decreased. Immediately, the rhythmic movements of the left upper abdomen ceased. When the previous pacemaker settings were then temporarily restored, the jerking movements of the upper abdomen at the rate of 70 beats/min were again noted. Rhythmic arm twitching could not be elicited by compression in the supraclavicular fossa or change in the patient's position. Later, at the time of repositioning the ventricular lead, the pulse generator was again reprogrammed to its initial settings; however, it did not induce diaphragmatic contractions. A chest radiograph showed that the distal end of the ventricular lead was now positioned in the right atrium (Fig. 3). Once again, the patient denied having manipulated the pulse generator. During repositioning of the pacemaker lead, the pulse generator could be moved freely within the large generator pocket. A tined ventricular lead was reinserted, and the pulse generator was tied into a Dacron® pouch, which was then sutured to the prepectoral fascia in several places with nonabsorbable sutures. During a 5-month follow-up, he was free of recurrent problems with normal pacemaker function.

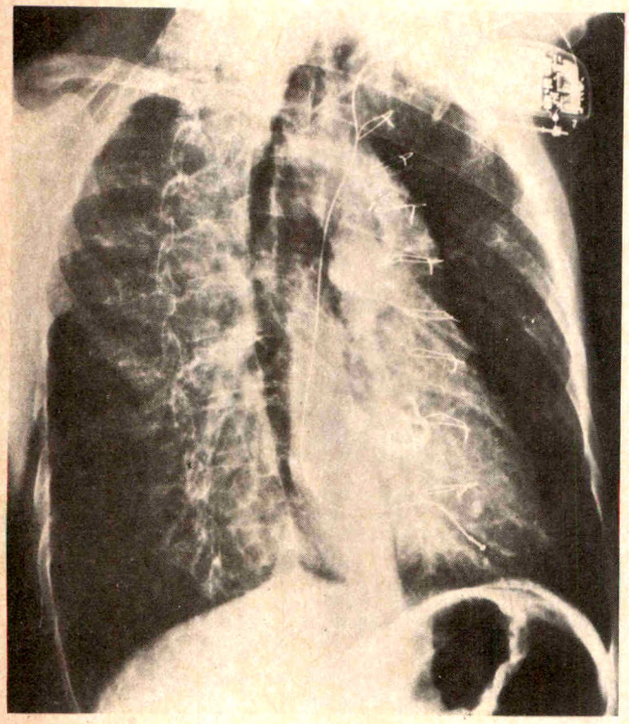

FIGURE 1. Chest radiograph (right anterior oblique position) after pacemaker implant showing tined lead at right ventricular apex.

Diaphragmatic pacing is usually associated with perforation of the right ventricle by the lead, but in our patient, as described in the classic syndrome, it was a result of ipsilateral phrenic nerve stimulation. The phrenic nerve enters the thorax by crossing from the lateral to the medial side, in front of the subclavin artery, and behind the subclavian vein just at the level of the clavicle.[5] This position corresponds to the electrode tip position seen on the chest radiograph. The pulse generator caused diaphragmatic pacing by phrenic nerve stimulation. This was confirmed in 2 ways: (1) When the lead tip was at the clavicle, changing the generator output controlled diaphragmatic pacing; and (2) after the patient manipulated the lead tip from the left subclavian vein to the right atrium, changing the

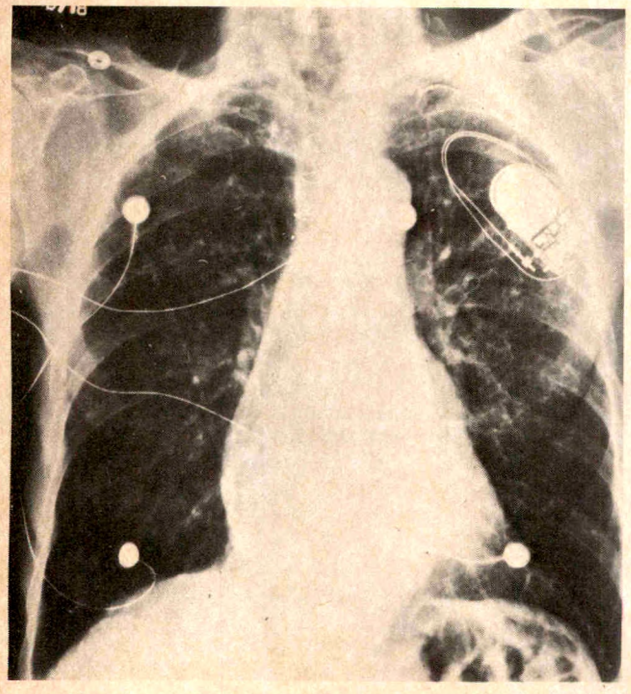

FIGURE 2. Chest radiograph on readmission during left diaphragmatic pacing. The lead tip is at the head of the first rib and the clavicle, where the phrenic nerve usually enters the thorax. The lead is wound around the pacer box by a "capstan effect."

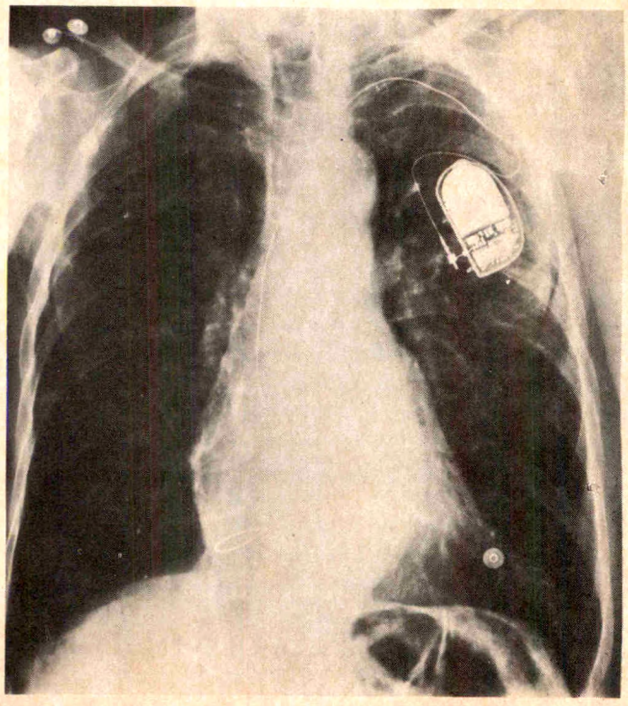

FIGURE 3. Chest radiograph just before reimplantation showing that the lead tip is now in the right atrium.

generator output failed to cause diaphragmatic pacing. With the use of tined leads, early lead dislodgement is infrequent (2 of 602 leads).[6] Lead dislodgement into the superior vena cava or the innominate vein with loss of pacer function and direct pacing of the phrenic nerve has not been previously reported with tined leads.

We believe that the broadened general use of the term PTS has obscured the original clinical syndrome with its interesting findings. Classic PTS and lead perforation should be considered when evaluating patients with pacemakers and diaphragmatic pacing.

Arrhythmogenic Right Ventricular Dysplasia in a Family

MICHAEL A. RUDER, MD
STUART A. WINSTON, DO
JESSE C. DAVIS, MD
JOSEPH A. ABBOTT, MD
MICHAEL ELDAR, MD
MELVIN M. SCHEINMAN, MD

Arrhythmogenic right ventricular dysplasia (ARVD) is an uncommon cardiomyopathy affecting primarily the right ventricle in which ventricular tachycardia of a left bundle branch block (LBBB) configuration is frequently the presenting finding.[1] We describe a family with a high incidence of ARVD documented by echocardiography or histologic examination of the heart.

Case 1: *A 21-year-old woman, the oldest of 5 siblings, was in apparent excellent health before dying suddenly while playing softball (Fig. 1). At autopsy, a markedly dilated and thin-walled right ventricle and a normal left ventricle were found. Histologic examination revealed prominent replacement of the myocardium with connective tissue.*

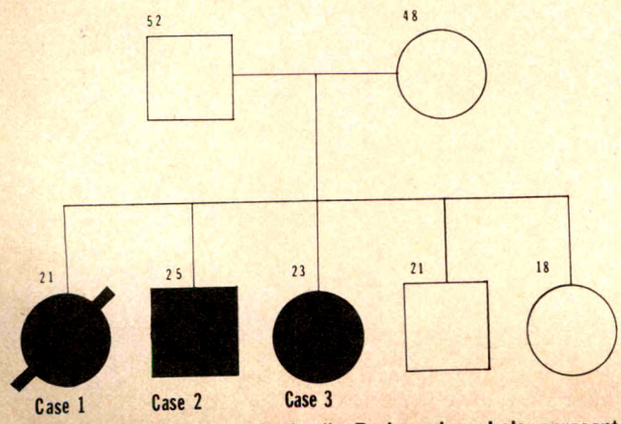

FIGURE 1. The pedigree of the family. **Darkened symbols** represent an affected member. Ages are given above the symbol.

Case 2: *A 25-year-old man had palpitations and presyncope while exercising. Results of physical examination were normal. A 24-hour electrocardiogram revealed nonsustained, monomorphic ventricular tachycardia with LBBB configuration at a cycle length of 420 ms. Electrocardiographic findings were normal except for an rSr′ pattern in lead V_1 and inverted T waves inferiorly and in leads V_1 to V_6. Chest radiograph showed a mild increase in heart size. Both echocardiography and radionuclide ventriculography showed a dilated, hypocontractile right ventricle with a normal left ventricle at rest.*

During electrophysiologic testing, sustained ventricular tachycardia identical to the clinical tachycardia was induced with programmed ventricular stimulation (Fig. 2). Sotalol therapy was effective in preventing tachycardia induction. A percutaneous ventricular biopsy specimen revealed extensive replacement of myocardium by fibrous tissue, confirming the diagnosis of ARVD. Immunochemical analysis of the specimen was normal. The patient is doing well with sotalol treatment at 6 months of follow-up.

Case 3: *A 23-year-old woman complained of short episodes of palpitations for the past 3 years. Results of physical examination were normal. Seventy-two-hour Holter monitoring showed several 3-beat salvos of ventricular tachycardia of LBBB configuration. T waves were inverted inferiorly and in leads V_1 to V_6. Chest radiograph was normal. Both echocardiography and radionuclide ventriculography showed right ventricular dilatation and hypocontractility with a*

Ventricular tachycardia in Case 2. **Top** to **bottom,** leads V_1, I and III, and intracardiac electrograms from the high right atrium (HRA), right ventricular apex (RVA) and right ventricular outflow tract (RVOT). The ventricular tachycardia has left bundle branch block pattern and a superior axis.

normal left ventricle. Ventricular tachycardia was not inducible during electrophysiologic testing. She continues to do well without antiarrhythmic therapy.

Family studies: *All other family members are asymptomatic and electrocardiograms and echocardiograms recorded for the remaining 2 siblings and both parents are normal.*

There have been several reports of ventricular tachycardia of LBBB configuration or of sudden deaths in relatives of patients with ARVD.[1–4] Although this is suggestive of a familial occurrence of ARVD, definitive evidence of organic disease of the right ventricle in these relatives was not obtained. Uhl's anomaly, which probably represents a more severe manifestation of ARVD, has been observed in family clusters.[5–7] The high incidence of affected siblings in the family described here (3 of 5) would appear to make a genetic pattern of autosomal recessive unlikely. A pattern of autosomal dominance with incomplete penetrance would appear to be more likely. Alternatively, familial exposure to a common toxic or infectious agent, perhaps with a genetic predisposition, is another possibility.

In view of the evidence presented that ARVD may be familial, we recommend that electrocardiograms and echocardiograms be obtained in family members. The role of antiarrhythmic prophylaxis for asymptomatic affected family members is not known.

Induction and Termination of Ventricular Tachycardia by Changing Body Posture

TOHRU OHE, MD
YOSIAKI TOMOBUCHI, MD
KATSURO SHIMOMURA, MD

In a limited number of cases, the initiation of ventricular tachycardia (VT) is related to body posture.[1] In this report, we describe a patient with VT that was initiated by assuming a supine position and terminated by standing.

A 27-year-old man presented with episodes of recurrent VT for 3 years. Physical examination and cardiac catheterization disclosed no significant abnormalities. An intracardiac electrogram during the tachycardia confirmed VT, and its origin was at the mid-inferior left ventricular wall (Fig. 1). Continuous monitoring repeatedly showed that VT occurred whenever he was recumbent. It lasted for 1 to 2 minutes when he stayed in a supine position, but was always terminated by standing (Fig. 2). The VT was terminated during a phase 2 Valsalva maneuver and resumed during a phase 4 Valsalva maneuver (Fig. 3). Intravenous (i.v.) injection of phenylephrine (0.2 mg) and volume loading with fluids induced VT. Pretreatment with i.v. atropine (1.0 mg) did not alter the characteristics of the initiation and termination of VT. Treadmill exercise testing and isoproterenol infusion (to 0.4 μg/min) failed to induce VT. There was no relation between heart rate and the occurrence of VT during these maneuvers. The echocardiogram verified that the initiation and termination of VT were closely related to left ventricular (LV) size. Figure 4 shows that LV size decreased during phase 2 Valsalva maneuver, at which time VT was terminated, while LV size increased during phase 4 Valsalva maneuver, at which time VT was initiated. Programmed ventricular stimulation did not induce VT nor terminate it, suggesting that the mechanism of VT was automaticity.

Characteristically, VT in our patient was initiated by assuming a supine position, by i.v. phenylephrine, by volume loading with fluids, and during a phase 4 Valsalva maneuver; it was terminated by standing and during a phase 2 Valsalva maneuver. Peters et al[1] described a case of VT that occurred only when the patient was in an upright position and always terminated when

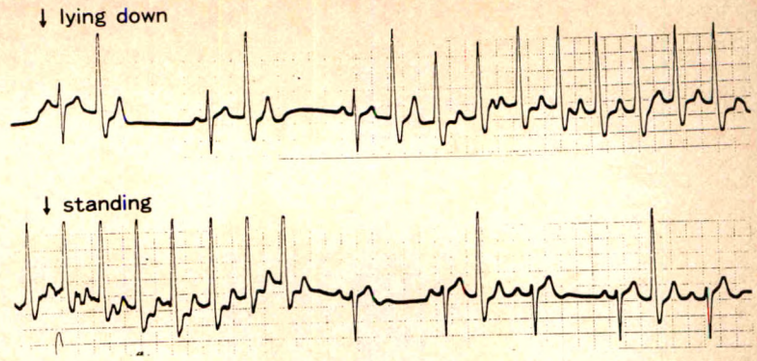

FIGURE 2. Continuous electrocardiographic monitoring showing that tachycardia is initiated by lying down and terminated by standing.

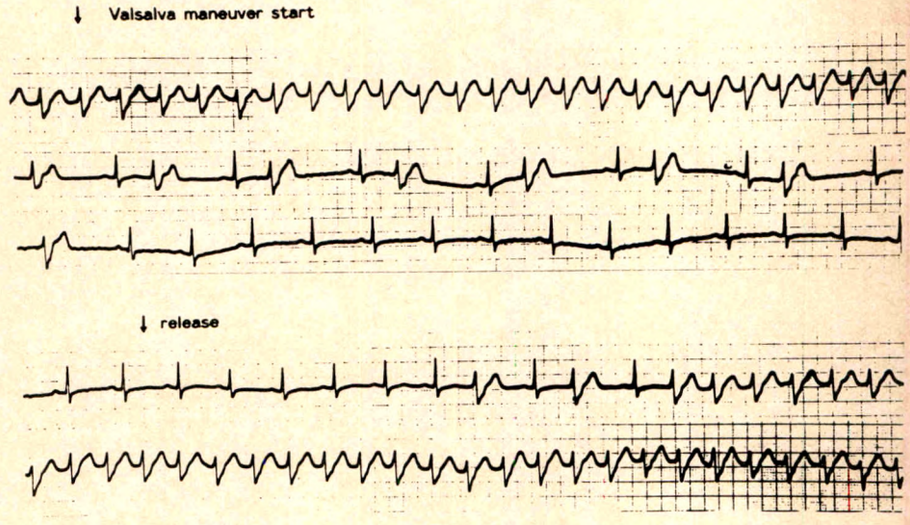

FIGURE 3. Continuous electrocardiographic monitoring during a Valsalva maneuver. Note that ventricular tachycardia is terminated during phase 2, and initiated during the phase 4 Valsalva maneuver.

the patient was lying down. They postulated that the attacks of VT were due to unusually strong sympathetic tone produced by assuming an upright position. In contrast, VT in the present patient was initiated by assuming a supine position and always terminated by standing. Some VTs were reported to have terminated by vagal stimuli.[2] Usually, the most effective vagal stimulation regarding termination of VT is produced by i.v. phenylephrine. In this patient VT was initiated, instead of terminated, by phenylephrine. Also, pretreatment with atropine did not alter the characteristics of the initiation and termination of VT. These findings suggest that neither sympathetic nor vagal stimuli plays an important role in the initiation and termination of VT in this patient. Change in heart rate is mechanism of induction of some VT. In this patient, VT was initiated not only during a phase 4 Valsalva maneuver when his heart rate increased, but also by phenylephrine injection when it decreased. A supine position, i.v. phenylephrine, volume loading with fluids, and phase 4 of the Valsalva maneuver—all of which induced VT in the present patient—increase LV size.[3,4] This was confirmed by measuring LV size with echocardiography during a Valsalva maneuver. Thus, it is possible that an increase in LV size was responsible for the occurrence

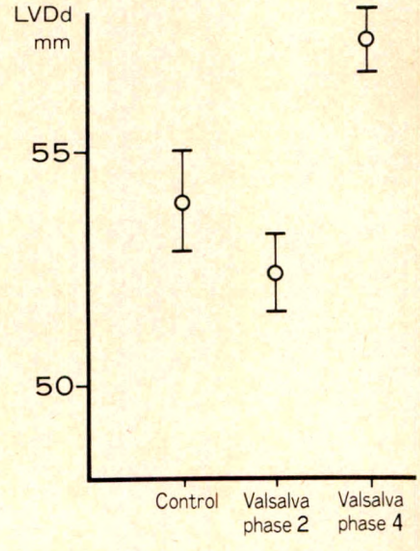

FIGURE 4. The change of end-diastolic dimension of the left ventricle (LVDd) during the Valsalva maneuver estimated echocardiographically. Note that LVDd decreases during phase 2, at which time the ventricular tachycardia is terminated, while the LVDd increases during phase 4, at which time the ventricular tachycardia is initiated. **Bars,** standard error of the mean.

of VT in this case. Recently, Waxman et al[3] reported 9 patients with VT that could be terminated by a Valsalva maneuver. They postulated that the termination was due to an abrupt reduction of cardiac size. The VT in this patient is unique in that not only the termination, but also the initiation of the VT were closely related to LV size.

Norepinephrine Infusions in Congestive Heart Failure

STEVEN R. GOLDSMITH, MD
GARY S. FRANCIS, MD
JAY N. COHN, MD

Norepinephrine (NE) levels are frequently increased in patients with congestive heart failure (CHF).[1,2] The significance of high circulating NE levels in patients with CHF is unknown. To provide data concerning the effects of an increase in plasma NE on hemodynamic function and plasma renin activity in CHF, we measured these variables in response to an infusion of exogenous NE in a group of 8 patients with CHF. Overall, the results do not suggest an important effect of circulating NE on either hemodynamic variables or plasma renin activity in CHF.

Eight patients participated in these studies. All patients had chronic CHF (New York Heart Association Functional Class II or III) of at least several months' duration but were in clinically stable condition at the time of study. Four had primary and 4 had ischemic cardiomyopathy. All had enlarged hearts on chest radiograph and decreased ejection fractions by either radionuclide scanning or echocardiography. All were receiving digitalis and diuretic therapy and some were taking vasodilators. None was taking α_1-blocking agents. All medications other than antiarrhythmic drugs were withheld on the day of study.

After all patients gave informed consent, hemodynamic monitoring was instituted with the patient in the postabsorptive state. After at least 30 minutes of rest following placement of Swan-Ganz and arterial catheters, baseline hemodynamic measurements were made and repeated 15 minutes later. If these values were within 10% of one another they were accepted as basal, with averaged values used as control measurements. Blood was then drawn from the arterial catheter for determination of plasma NE and renin activity. An infusion of Levophed® (L-NE) was then begun into a peripheral vein at 0.1 μg/min and subsequently increased to 0.5 μg/min, and then to 1.0, 1.5 and 2.5 μg/min. Each infusion rate was maintained for 20 minutes, with hemodynamic measurements made between the 10th and 20th minute of each stage, and blood resampled for NE and renin just before increasing to the next level. At the conclusion of the 2.5-μg/min infusion, blood was sampled a final time and the study concluded.

Plasma for NE analysis was separated immediately by cold centrifugation, frozen and stored at −20°F for later analysis by radioenzymatic assay[3]; in our laboratory this has an inter- and intraassay coefficient of variation under 8%. Plasma renin activity was measured by radioimmunoassay[4] with similar reliability in our laboratory.

All data were analyzed using analysis of variance for repeated measures on the same elements.

Baseline hemodynamic variables in those patients with CHF included a heart rate of 79 ± 8.5 beats/min, mean arterial pressure of 79 ± 10 mm Hg, cardiac index of 2.5 ± 0.56 liter/min/m^2 and systemic vascular resistance of 1,272 ± 311 dynes cm^{-5}. Right atrial pressure was 12 ± 7 mm Hg and left ventricular filling pressure, estimate from either one pulmonary capillary wedge or pulmonary artery diastolic pressure, was 26 ± 5 mm Hg. None of these variables changed significantly in response to the increase in plasma NE levels from 730 ± 368 pg/ml (baseline) to 2,532 ± 1,326 pg/ml at the 2.5 μg/min level (Fig. 1). Plasma renin activity, 1.5 ± 0.54 ng/ml/hour, also did not change during the infusion.

These observations indicate that exogenous infusions of L-NE, which produce plasma levels comparable to those found during maximal exercise,[5] do not cause significant hemodynamic effects in patients with CHF. Silverberg et al[6] and Izzo (7) showed that in normal subjects, 2-fold or greater increases in plasma NE levels do raise blood pressure and reduce heart rate. Since with comparable or greater absolute and relative increases in plasma NE over baseline in heart failure we saw no hemodynamic changes, our data suggest a blunted peripheral vascular response to circulating NE in this condition with the lack of reflex bradycardia as a consequence.

A blunted blood pressure response to infused NE could be a consequence of "down regulation" of α_1-adrenergic receptors exposed to the chronically high levels of NE found in patients with CHF.[1,2] Such down regulation has recently been demonstrated in vascular smooth muscle.[8] Alternatively, the blunted response could be due to changes in number or sensitivity of peripheral α_2-adrenergic receptors, because they also may influence peripheral vascular resistance and may be more responsive to circulating as opposed to neuronally released NE.[9] Platelet α_2 receptors are decreased in CHF,[10] although we have no direct information concerning the postsynaptic α_2 receptor. Overall, down regulation of α receptors would not be surprising in

This study was supported by Grant HL22977-03 from the National Heart, Lung, and Blood Institute, Bethesda, Maryland, and by a research grant from the Veterans Administration, Washington, D.C. Manuscript received February 13, 1985; revised manuscript received May 10, 1985. Accepted May 13, 1985.

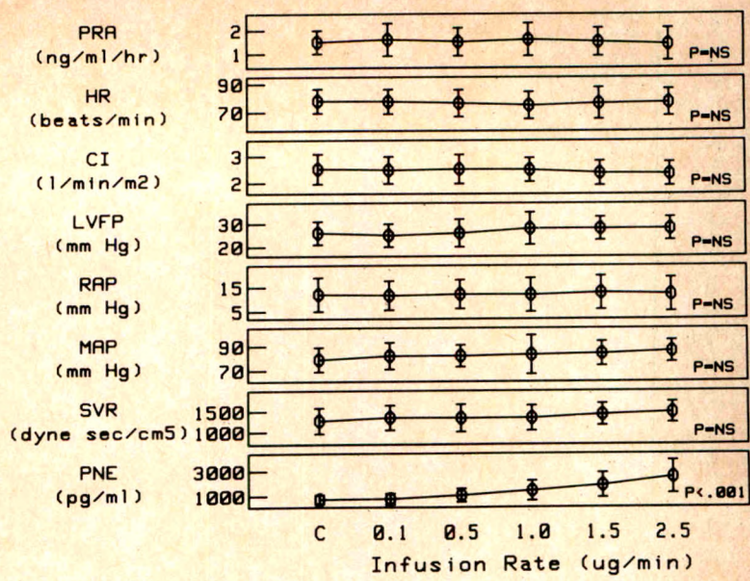

FIGURE 1. Response of plasma norepinephrine (PNE), plasma renin activity (PRA), heart rate (HR), mean arterial pressure (MAP), cardiac index (CI), systemic vascular resistance (SVR) and left ventricular filling pressure (LVFP) to exogenous norepinephrine infusions in patients with congestive heart failure (n = 8). Values are expressed as ± standard error of the mean. NS = not significant; RAP = right atrial pressure.

patients with CHF in view of the well documented down regulation of β receptors in this condition.[11,12]

The lack of hemodynamic effects during an exogenous NE infusion does not necessarily bear on the effects of endogenously released NE in patients either in the basal state or during stress. Plasma NE measured during endogenous stress represents only a small fraction of total NE released, because most is either taken up into the presynaptic nerve terminal or immediately metabolized in the synaptic cleft.[13] Hence, a given plasma level of NE produced by endogenous stress represents a much higher total NE response than that produced by an infusion. Nonetheless, these data do show that circulating NE itself, at the levels produced here, does not have a marked circulatory effect in patients with CHF. Any contribution of plasma NE as a circulating hormone to the vasoconstriction produced by a stimulus such as exercise is therefore likely to be minimal. The fact that vasoconstriction in nonexercising muscle beds does occur during exercise in patients with CHF,[14] strongly militates against another possible explanation for the current results—that NE-induced vasoconstriction is maximal or near-maximal in the basal state and therefore not amenable to further change by exogenously increased levels of circulating NE. Also in opposition to this interpretation is the observation that patients with CHF can respond in normal or even exaggerated fashion to infusion of another vasoconstrictor such as vasopressin.[15]

There was also no change in plasma renin activity during the infusions. Because plasma renin levels were essentially normal in this group of stable patients, it is unlikely that excessive baseline stimulation would account for the lack of response to the infused NE. Also, because there were no significant hemodynamic effects, a reflexly mediated decrease in renin activity probably did not offset any direct stimulation. Again, because synaptic cleft NE levels may be much higher than those in the plasma, circulating plasma NE levels in the range produced here may not be adequate to stimulate renin release by adrenergic mechanisms. However, as with the lack of vasoconstrictor response, an alternative possibility is down regulation of the renal β receptors responsible for mediating sympathetically induced renin release. This interpretation is buttressed by Izzo's study in normal subjects[7] in whom small changes in NE were associated with clear increases in plasma renin activity.

In summary, infusions of L-NE, which produced plasma NE levels of approximately 2,500 pg/ml, were without significant effects on either hemodynamic variables or renin activity in 8 patients with CHF. Although the role of endogenous sympathetic stimulation on hemodynamic variables and renin release is not resolved, the results do suggest a lack of any important effect on these variables from plasma levels of NE per se, and may point to altered peripheral adrenergic receptor activity in patients with this disease.

Acknowledgment: We thank Susan Ziesche, Dennis Lura and Terry Cameron for their technical help in performing the studies; Ada Simon for performing the norepinephrine and renin determinations; Darryl Erlien for help with the statistics and graphics, and Belinda Anderson for preparing the manuscript.

Upright Paradoxical Posterior Wall Movement in Mitral Valve Prolapse

JACK KRAFCHEK, MD
MARY SHAW, RDMS
JOSEPH KISSLO, MD

Upright exercise 2-dimensional echocardiography (2-D echo) is being used frequently to evaluate patients with suspected coronary artery disease (CAD).[1] As with other techniques, this diagnosis is suggested when segmental wall motion abnormalities appear with exercise. We have noted the spontaneous development of high posterior wall motion abnormalities during casual upright 2-D echo that were not present in the study during supine rest. These abnormalities appeared to be more obvious in patients with known or suspected mitral valve prolapse (MVP). This study documents the prevalence of a postural phenomenon in patients with MVP.

From the Department of Medicine, Division of Cardiology, Duke University Medical Center, Durham, North Carolina 27710. This study was supported in part by Grants HL-12715, CA-37586 and HL-07063 from the U.S. Public Health Service, Bethesda, Maryland. Manuscript received February 25, 1985; revised manuscript received April 19, 1985, accepted April 23, 1985.

Forty-six subjects were studied and were separated into 2 groups on the basis of the absence or presence of MVP by 2-D echo. MVP by 2-D echo was defined as systolic movement of 1 or both of the mitral valve leaflets into the left atrium and breaking the plane of the mitral valve anulus.[2] The non-MVP group consisted of 19 normal volunteers, aged 20 to 48 years (mean 33). The MVP group consisted of 27 persons, aged 22 to 45 years (mean 30), with definite auscultatory and 2-D echocardiographic evidence for MVP (15 with clicks alone and 12 with clicks and late systolic murmurs). No person had historical, physical or electrocardiographic evidence for CAD or any other form of heart disease and, except for findings of MVP, the 2-D echocardiographic results were normal. Except for 3 subjects with MVP who were receiving diuretic drugs, the study population was free from medication.

Complete 2-D echocardiographic examinations in all standard views were performed with the patient in the re-

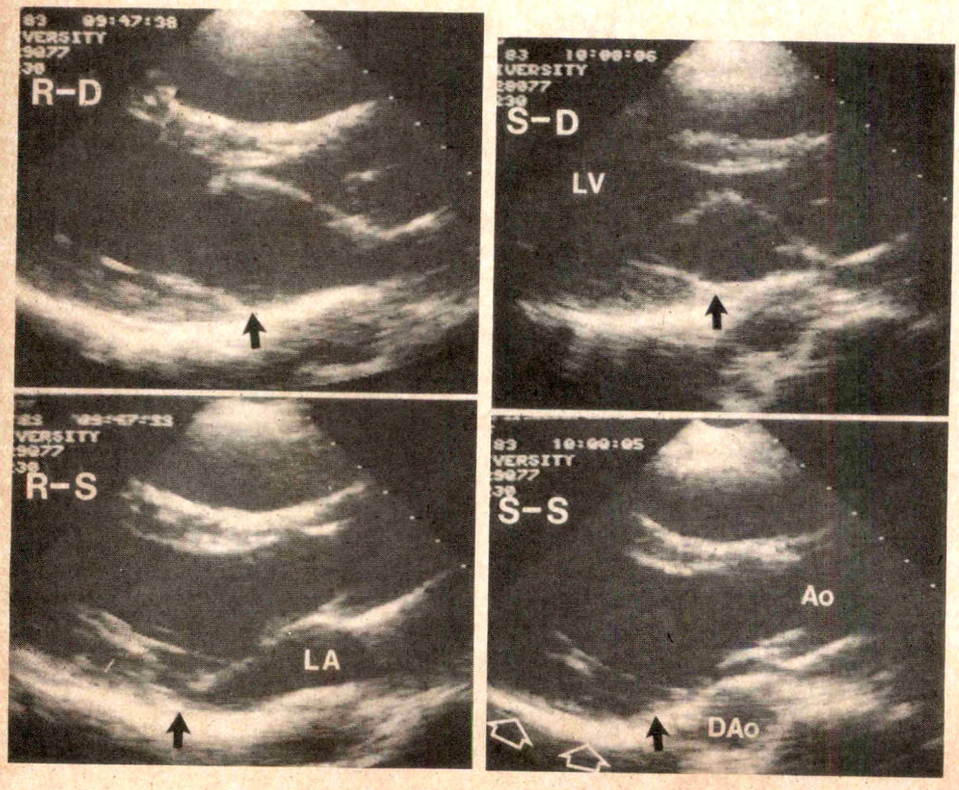

FIGURE 1. Composite long-axis recumbent views in diastole (R-D) and systole (R-S) as well as standing diastole (S-D) and systole (S-S) from a patient in group II, with more extensive changes during standing systole (**open arrows,** panel S-S). **Black arrows** indicate position of posterior mitral anulus. Ao = aortic root; DAo = descending aorta; LA = left atrium; LV = left ventricle.

cumbent, 30° left lateral and then upright positions using commercially available imaging systems with 3.5- or 2.5-MHz transducers. In addition, the last 6 MVP patients studied were also examined in the sitting position. Derived dual M-mode echocardiograms better displayed the induced wall motion abnormalities and were recorded while imaging in the parasternal long axis projection. Cursor A was placed through the high posterior ventricular wall just below the mitral valve anulus and cursor B was positioned through the left ventricular wall just above the papillary muscle. At no time did cursor A intercept the anulus or left atrium. All echocardiographic data were reviewed independently by 2 experienced observers and agreement by both as to the presence or absence of MVP and wall motion abnormalities was required.

All 19 normal subjects showed normal posterior wall motion in the recumbent position. Sixteen showed no change in the normal pattern of posterior wall motion when standing. However, 3 (16%) showed mild posterior wall dyskinesia when standing; 2 of them had equivocal MVP and 1 definitely did not have MVP.

Similarly, all 27 patients with MVP showed normal recumbent wall motion. When sitting, 4 of the 6 patients examined showed mild but obvious high posterior wall dyskinesia. Upon standing, every subject (100%) with MVP showed clearly evident dyskinesia of the high posterior wall (more severe compared with changes noted in the sitting position). In 21 patients, this abnormality was confined to the upper third of the posterior wall. In 6 patients, dyskinesia of the upper posterior wall was profound and extended more toward the ventricular apex (Fig. 1 and 2) and into the posterolateral wall.

This study shows that in patients with MVP and normal supine wall motion, significant posterior ventricular wall dyskinesia can develop when a standing position is assumed. Less significant dyskinesia can also be seen in some patients while sitting. In those in whom the subjective severity of the MVP was more severe, the extent and amount of dyskinesia was greater.

More than 20 years ago, Keats and Martt[3] made the initial flouroscopic observations of spontaneous high posterior wall motion abnormalities in the standing position. Inhomogeneity of normal left ventricular contraction has also been known for many years, with the high posterior wall showing later and less contractility compared with other wall segments in normal subjects.[4] The geometry and pattern of ventricular contraction can also be variable and dependent on volume loading conditions.[5,6] Few studies have closely examined wall motion changes occurring in upright posture, and since standing is accompanied by a decreased preload and chamber size,[7] some alteration of contractility and geometry may be expected.

Abnormal contractile patterns of the basal and posterior wall in the recumbent position are well recognized in some patients with MVP.[2,8,9] Abnormal biochemical and myocardial histologic characteristics have also been found.[10] No consensus exists, however, as to whether these changes represent a primary local myocardial problem or are induced secondary to MVP itself.

All subjects in the present study had normal wall motion in the supine position and all those with MVP had clear-cut dyskinesia from recumbent to standing positions. This phenomenon was probably not a result of positional artifact because dyskinesia was observed in more than 1 view. Similarly, we did not observe any recumbent/standing changes in electrocardiographic morphologic pattern to suggest an altered depolarization or conduction pattern.

This phenomenon may have multiple causes. First, decreased preload while standing may induce this phenomenon, given the many abnormalities associated with MVP (such as anular movement). Second, spatial geometric changes of the heart relative to other structures may be responsible. All subjects showed a decrease in left atrial size while standing, with an altered relation between left atrium and descending aorta. The mitral ring moved more inferiorly and posteriorly upon standing in patients with MVP than in normal subjects. In fact, the descending aorta impinged on the left atrial cavity from behind in some cases and appeared to restrict the movement of the anulus (Fig. 1). Third, the close proximity between taut chordae and endocardium may cause systolic mural compression.[9]

The results of this study have several important implications. As the use of 2-D echo in the sitting position or standing during upright exercise becomes more widespread, false-positive responses for CAD may occur unless the presence of MVP is suspected and these spontaneous changes are documented. The development of this abnormality also raises the possibility of an additional cause of the enhanced mitral murmur of

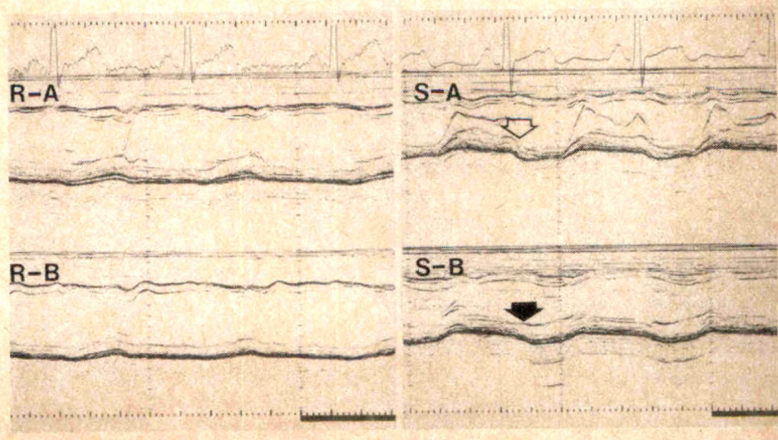

FIGURE 2. Dual M-mode traces from the same patient as in Figure 1, with normal posterior wall motion in the recumbent position (**left,** panel R-A). Upon standing (**right,** panel R-B), extensive paradoxic changes are noted in both the high (**open arrow,** S-A) and middle (**closed arrow,** S-B) back wall. R-A = recumbent just above papillary muscles; R-B = recumbent lower in ventricle; S-A = standing just above papillary muscles; S-B = standing lower in ventricle.

MVP on standing. Finally, the high incidence of the development of this dyskinesia in the upright position in patients with MVP suggests that it may be a useful provocative test for this entity.

Safety of Labor and Delivery in Women with Mitral Valve Prolapse

EDWARD P. SHAPIRO, MD
EDWARD L. TRIMBLE, MD
J. COURTLAND ROBINSON, MD
MYRNA T. ESTRUCH, MD
SHELDON H. GOTTLIEB, MD

Because mitral valve prolapse (MVP) is associated with joint laxity, musculoskeletal abnormalities and distinctive anthropometric characteristics, and is present in most cases of the Marfan syndrome and the Ehlers-Danlos syndrome, the valve disorder probably represents the cardiovascular manifestation of a generalized disorder of connective tissue.[1] Fuenzalida[2] suggested that laxity of joints and connective tissue may facilitate pregnancy and childbirth, conferring a selective advantage to those who carry the MVP gene (or genes) and counteracting any natural selective presssure against the syndrome. Indeed, the gene appears to be most penetrant in women[3] and clinical aspects of this syndrome are most manifest during the childbearing years. Rayburn and Fontana[4] showed that pregnancy and childbirth were safe in women with MVP, but possible advantages of the syndrome were not examined. This study was designed to evaluate the ease and efficiency of labor and delivery in women with MVP.

The records of labor and delivery were evaluated in 23 patients with auscultatory and echocardiographic evidence for MVP, detected before the onset of labor, after 1981. All patients had abnormal findings on cardiac examination by their obstetrician and were therefore referred to a cardiologist. MVP was diagnosed if both a mid- to late apical systolic click or murmur was heard and M-mode echocardiography demonstrated at least 2 mm of pansystolic bowing or midsystolic buckling of the CD segment of the mitral tracing. A control was assigned to each patient, selected as the next patient delivering, matched for parity, age (within 2 years), race and infant birth weight (within 500 g). All control subjects had normal heart sounds on screening examinations by their obstetrician.

The rate of cervical dilatation during active labor, which accurately reflects the overall efficiency of labor,[5] was considered the major outcome variable. This value was determined by plotting cervical os diameter vs time (Freidman's curve) and measuring the rate at the maximal slope during the active phase of labor.[5] The duration of the first stage of labor was defined as the time between the onset of regular contractions and full cervical dilatation. The duration of the second stage of labor was measured from the time of full dilatation to delivery. For comparisons of infant birth weight and Apgar scores, a second group of control subjects was selected as above, except that infant birth weight was not matched. Weight before pregnancy and height were recorded and the ponderal index was calculated as the cube root of the body weight divided by the height, times 100. The highest systolic blood pressure during pregnancy was noted.

Statistical analysis was performed with paired t-tests, with pairs matched as described above, to facilitate control of variables known to influence the ease of labor and to isolate, as far as possible, the effects of MVP. Four pairs in which cesarean section or pitocin augmentation was required for either the patient or control were excluded in analysis of duration of labor and rate of cervical dilatation. Statistical power analysis was performed by the method of Young et al,[6] considering the rate of cervical dilatation at the maximal slope as the major outcome variable, with differences in the rate of dilatation of less than 2 cm/hour judged not to be of practical importance.

Patients with MVP weighed significantly less than control subjects and had a significantly lower ponderal index (Table I). The peak systolic blood pressure during pregnancy was 117 mm Hg in patients with MVP and 121 mm Hg in control subjects, but the difference was not statistically significant (2-tailed, $p = 0.07$). The rate of cervical dilatation at the maximal slope was 3.3 cm/hour in both patients and control subjects (difference not significant). With the given sample size and standard deviation, a difference of 1.1 cm/hour or greater could have been detected ($\alpha = 0.05$) with 80% certainty ($\beta = 0.20$).[6] The duration of the first and second stages of labor was not different in the 2 groups (Table I). Two patients and 1 control subject required cesarean section for breech presentation or failure of labor to progress. Two patients and 3 control subjects required pitocin augmentation. Birth weights and Apgar scores were similar in both groups. Thus, there were no statistically or physiologically signifi-

BP = blood pressure; C-section = cesarean section; MVP = patients with mitral valve prolapse; NS = not significant.

cant differences in the ease or efficiency of labor between these groups.

This study confirms that labor and delivery are safe in MVP, but provides no evidence for an advantage acting through joint laxity or distensible connective tissue during childbirth. The rate of cervical dilatation at the maximal slope provides an excellent measure of the overall efficiency of labor[5] and was used in this study as an indirect predictor of morbidity, since direct comparison of the rates of complications of labor, which are uncommon in our population, would have required very large sample sizes. Our inability to detect a difference is not likely a result of inadvertant dilution of the control group with patients with silent mitral valve prolapse, because the 2 groups showed expected differences in ponderal index and weight[7] and only patients with marked and unequivocal valvular abnormalities were selected for the study.

Differential fertility is an important agent of natural selection and is a logical consideration in justifying the high frequency of an inherited condition which predominately affects young women. Although we have shown no clinically significant advantage over the general population in the speed of labor and delivery, small differences which are not detectible by our methods could become important over very long time periods. Therefore, although not supported by our data, the hypothesis presented by Fuenzalida[2] cannot be absolutely excluded. Alternatively, any life-threatening complications associated with mitral valve prolapse may occur after the most fertile childbearing years in most instances, so that selective pressure against the syndrome is weak or nonexistent.

Mitral Valve Prolapse and Addictions

JON CHRISTOPHER STRINGER, MD
ANIS OBEID, MD
ELEANOR O'SHEA, RN, CNP

Mitral valve prolapse (MVP) is a common inherited disorder with a prevalence believed to be between 5 and 10% in the general population.[1] MVP is associated with an array of psychiatric diagnoses, including anxiety neurosis and panic attacks,[2] agoraphobia,[3] depression[4] and sleep disorders.[5] Autonomic dysfunction and elevation of plasma catecholamine levels have also been described,[6] suggesting that the valvular abnormality is part of a generalized neuroendocrine-cardiovascular disorder. During a 2-year period in a general hospital-based Substance Abuse Detoxification Unit, MVP appeared to occur more frequently than would have been expected in a randomly selected population. This report presents the results of a study designed to document the prevalence of MVP in patients who abuse psychoactive drugs and seek detoxification.

One hundred one consecutive patients (69 men, 32 women) were admitted to the Substance Abuse Detoxification Unit of Crouse Irving Memorial Hospital because of significant and continuing physical, interpersonal and occupational problems related to psychoactive drug abuse. They were 18 to 68 years old. All patients were unable to control use of addicting psychoactive drugs.

Fifty-six of the patients had systolic clicks with or without mid- to late systolic murmurs by auscultation in supine or standing positions. Of these 56 patients, 48 were then studied by 2-dimensional (2-D) and M-mode echocardiography using phased-array equipment (Toshiba model SSH10A or Hewlett Packard model 77020A) and 2.25-MHz transducer. The other 8 patients signed out against medical advice before echocardiographic study. Complete echocardiographic examination was performed using standard long- and short-axis views, as well as apical 4-chamber and subxiphoid positions. All studies were performed by experienced technicians with a senior cardiologist in attendance. The studies were reviewed for technical quality and further footage recorded by the cardiologist if necessary. M-mode records were derived from the 2-D examination and the data were used in the measurement of the cavity dimensions and wall thickness. MVP was diagnosed entirely on the basis of the 2-D study, following the criteria of Gilbert et al[7] and Morganroth et al.[8] When displacement of the anterior or posterior mitral leaflets or both was noted posterior to the mitral ring in either the long axis view or the apical four chamber view, MVP was considered to be present. All the records were reviewed by one of the investigators and MVP was diagnosed only when the above criteria were met.

Fifty-six patients had physical signs of MVP (mid- to late systolic click with or without systolic murmur), and 38 of these 56 patients had echocardiographic confirmation of the diagnosis. In the remaining 17 patients, the clinical evidence for MVP was not confirmed by echocardiography. However, 8 of these 17 left the hospital against medical advice before being studied. The occurrence of echocardiographically confirmed MVP in 37% of the patients admitted to the detoxification unit is substantially greater than the 5% to 10% prevalence of MVP expected in a randomly selected population.[1]

MVP was slightly less prevalent in the alcoholic patients than those admitted for abuse of other drugs (nonalcoholic sedatives, cocaine/amphetamines, opiates and multiple drug abuse) by the criteria of physical examination or echocardiography, but the number of patients in each group was too small for significant statistical analysis. Women admitted to our detoxification unit were more likely than men to have MVP by physical examination criteria ($p < 0.05$). This likelihood appears even more pronounced when echocardiographic criteria are used ($p < 0.025$). However, this may be influenced by the fact that 8 men but no women left the hospital against medical advice before being studied.

MVP may have been detectable by echocardiographic criteria in more than the 39 patients indicated in Table I. Some of the 45 patients with no clinical evidence for MVP likely had silent MVP. Further provocative testing with amyl nitrate was not done in the 9 patients with clinical evidence for MVP but negative echocardiographic findings. Finally, 8 patients with clinical evidence for MVP left the hospital against medical advice prior to being studied.

Patients with MVP often have associated dysphorias.[2–5] Vasomotor instability and elevation of plasma catecholamine levels have also been described.[6] Seeking relief from these symptoms, many patients with MVP enter the health care delivery system and are treated with medications such as β-blockers, antidepressants and sedatives. Addiction to sedatives, especially benzodiazapines, is a risk for these patients. The results of

Signed out AMA before being studied	8(7%)	8(13%)	0(0%)	3(4%)	3(8%)	0(0%)	5(14%)	5(2%)	0(0%)
Studied by echo	48(46%)	22(35%)	26(67%)	25(46%)	12(32%)	13(65%)	23(52%)	10(4%)	13(68%)
+ Clinical exam but − MVP by echo	10(9%)	6(10%)	4(9%)	5(11%)	2(5%)	3(2%)	5(8%)	4(2%)	1(5%)
+ Click ± murmur and with MVP by echo	38(37%)	16(26%)	22(58%)	20(35%)	10(27%)	10(50%)	18(42%)	6(24%)	12(67%)

* Sedatives (other than alcohol), cocaine/amphetamines, opiates and multiple drug abuse.
AMA = against medical advice; Detox = detoxification; echo = echocardiogram; MVP = mitral valve prolapse.

this study suggest that some patients with MVP may self-medicate with psychoactive drugs in attempts to modulate some or all of these same dysphorias. Tolerance and loss of control supervene and, for many, addiction occurs.

Of the 39 patients with MVP documented by echocardiography, 23 had clear family histories of alcoholism (either parents, grandparents or aunts/uncles). This is consistent with studies that show that the offspring of alcoholics are more likely to have the same disease than the offspring of non-alcoholics. The role of environment in this issue has been minimized in Scandanavian adoption studies, and there is at least a 4 times increased risk for the adopted male offspring of an alcoholic biologic parent to develop alcoholism even when reared in homes where alcoholism is not present.[9] Further, behavioral and neurochemical studies have shown that certain genetic strains of mice prefer and seek out alcohol in laboratory feeding selections and become addicted when compared to other strains of mice. These addiction-prone mice have baseline deficiencies in whole brain met-enkephalin.[10]

Thus, there is evidence for a genetic neuroendocrinologic basis for the inability to control appetite for psychoactive drugs. MVP may be a marker for an increased risk of developing substance abuse and addiction. Further study directed toward identifying endorphin abnormalities in the disorder of MVP and in addiction-prone families may lead to a greater understanding of the personality prone to addiction.

This study suggests that patients with MVP are overrepresented in the population of substance abusers requiring detoxification. Practitioners should try to identify these patients in order to evaluate and counsel them regarding symptoms and complications of the MVP syndrome. Particular attention should be paid to the risks of using intravenous drugs in patients with MVP because of the inherent risks of developing infective endocarditis.

Significance of E Point–Septal Separation by M-Mode Echocardiography in Patients with Aortic Regurgitation

MAXINE H. ROSOFF, MD
MICHAEL V. COHEN, MD

Separation between the mitral E point and left side of the ventricular septum on M-mode echocardiography has been shown to be a practical index of left ventricular (LV) performance in adults and children with unrestricted motion of the mitral valve.[1–4] Patients with aortic regurgitation (AR) are usually excluded from studies of E point–septal separation (EPSS) because of the possibility of abnormal mitral valve motion, and echocardiography performed on a few of these patients has revealed no consistent relation to contractile function.[1] To evaluate the significance of EPSS in this disorder, we retrospectively examined M-mode echocardiograms of 56 patients who underwent cardiac catheterization for AR.

From the Division of Cardiology, Department of Medicine, Montefiore Medical Center and Albert Einstein College of Medicine, Bronx, New York. Manuscript received January 28, 1985; revised manuscript received April 23, 1985, accepted April 27, 1985.

The records of all adult patients who underwent cardiac catheterization at Montefiore Medical Center between December 1974 and April 1984 were reviewed. Fifty-six patients with isolated moderate or severe AR, 37 men and 19 women between ages 19 and 84 years, had technically adequate echocardiographic and angiographic studies. Patients were excluded if either the M-mode echocardiogram or angiogram was inadequate, or if mitral stenosis, mitral regurgitation, aortic stenosis or pulmonary hypertension (pulmonary artery systolic pressure 55 mm Hg or greater) coexisted.

Echocardiograms were performed with either an Irex 101 M-mode echocardiograph and 2.25-MHz transducer coupled to a Honeywell strip-chart recorder or a Hoffrel model 101 ultrasonoscope. Patients were studied in the left lateral decubitus position with varying degrees of rotation. The mitral valve was recorded at the position where both leaflets were visualized and mitral excursion was greatest. Studies were excluded if either the left side of the septum or mitral valve was poorly visualized, or if marked diastolic fluttering of the anterior mitral leaflet obscured the E point. EPSS 1 was defined as the vertical distance from the leading edge of the left septal echo to the simultaneously recorded leading edge of the mitral valve at its most anterior position in early diastole (Fig. 1). EPSS 2 was defined as the vertical distance from a horizontal line drawn through the left side of the

septum at its most posterior position in the cardiac cycle to the mitral valve E point (Fig. 1). EPSS was evaluated in 10 consecutive beats, and the minimal value was accepted.

Cardiac catheterization was performed within 15 days of echocardiography, and in most cases it was done the next day. Biplane angiography was performed in the right and left anterior oblique projections. Left ventricular systolic and diastolic volumes were calculated using the Dodge method.[5] *In 43 patients, cardiac output was determined by the Fick method.*

Fifty-six subjects with moderate or severe AR had technically adequate angiograms and echocardiograms, and no evidence of other significant valvular lesions. EPSS 1 exceeded EPSS 2 by 4 to 7 mm in 9 patients. In all other patients, EPSS 1 was 0 to 3 mm greater than EPSS 2.

Nineteen of 56 patients (34%) had an ejection fraction (EF) greater than 55% with EPSS more than 10 mm. Figure 1 is a representative mitral valve echogram in a patient with severe AR secondary to a biscuspid aortic valve. Despite a normal EF of 62%, EPSS is greatly increased to 30 mm. Cardiac output and LV end-diastolic pressure were both normal in this patient. For all patients studied, the relation between EPSS 1 and LV function as assessed by angiographic EF is shown in Figure 2. Linear regression analysis yielded a poor negative correlation between EPSS and EF, with $r = -0.48$ for EPSS 1 and $r = -0.47$ for EPSS 2. No value for EPSS clearly separated patients with normal and abnormal EF. Among 20 patients with depressed EF, however, only 3 had normal EPSS.

Figure 3 shows the relation between EPSS 1 and LV end-diastolic volume in 46 patients in whom this volume was quantitated. Although there is a tendency for greater LV volume to be associated with higher EPSS, correlation was poor ($r = 0.57$). Using EPSS 2, $r = 0.61$. No value for EPSS classified patients into groups with mildly and severely increased LV end-diastolic volumes, although all patients with volumes greater than 305 ml had EPSS of at least 15 mm. Among 43 patients in whom cardiac output was determined, there was no correlation with EPSS ($r = -0.04$). EPSS 1 exceeded 10 mm in 55% of patients with fluttering of the mitral valve by echocardiography and in 56% of those without fluttering.

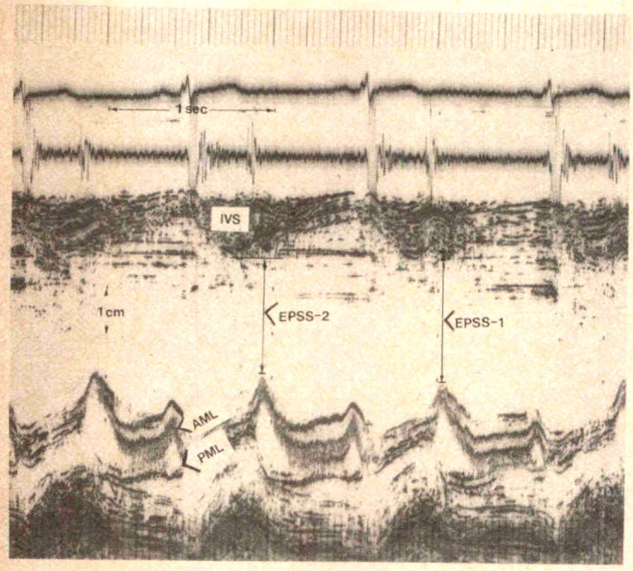

FIGURE 1. M-mode echocardiogram at the level of the mitral valve in a patient with severe aortic regurgitation, illustrating the method used to measure E point-septal separation (EPSS) 1 and EPSS 2. This patient had an ejection fraction of 62%, but EPSS 1 and 2 were increased to 30 and 28 mm, respectively. AML = anterior mitral leaflet; IVS = ventricular septum; PML = posterior mitral leaflet.

Although increased EPSS appears to be associated with larger ventricles and poorer systolic function in patients with AR, correlation is poor for individual patients. In 1977, Massie et al[1] described the association of increased EPSS and reduced LV systolic function in patients with no AR or mitral stenosis, and found that a value of at least 5 mm for EPSS 1 correlated strongly (r = 0.87) with reduced angiographic EF. D'Cruz et al[2] and Lew et al[3] later suggested EPSS up to 6 mm was normal, and confirmed the association between increased EPSS and LV dysfunction. Child et al[4] compared patients with MR and no LV failure with those having either dilated or amyloid cardiomyopathy, and found that EPSS of at least 6 mm accurately identified

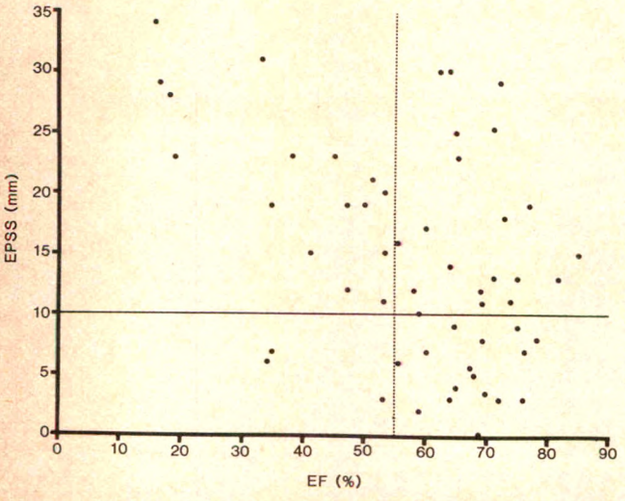

FIGURE 2. Relation of E point-septal separation (EPSS) 1 to angiographic left ventricular ejection fraction (EF) in patients with moderate to severe aortic regurgitation. Correlation between these parameters is weak (r = −0.48).

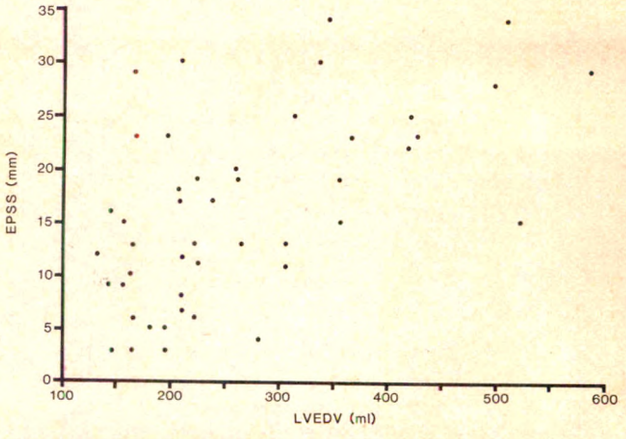

FIGURE 3. Relation of E point-septal separation (EPPS) 1 to angiographic left ventricular end-diastolic volume (LVEDV) in patients with moderate to severe aortic regurgitation. There is weak correlation between these parameters (r = 0.57).

patients with EF less than 55%, irrespective of LV size, although patients with dilated cardiomyopathy tended to have greater EPSS than those with restrictive disease.

We chose to define EPSS as the instantaneous vertical distance from the left side of the ventricular septum to the E point, and compared these measurements with those derived by the method described by Massie et al.[1] Since the original M-mode studies were done, 2-dimensional echocardiography has demonstrated that motion of the heart within the thorax causes the wall segments imaged by M-mode tomography to vary during the cardiac cycle.[6] Simultaneous EPSS, therefore, may be expected to be a more accurate reflection of the distance between the septum and mitral valve. There was no significant difference in correlation between LV volume or EF and EPSS measured by either method.

One explanation for the poor correlation between EF and EPSS is chamber dilatation secondary to AR. If this were the case, however, correlation between diastolic volume and EPSS might be expected to be stronger. In some cases, marked fluttering of the anterior mitral leaflet in the presence of AR might have obscured the true E point. However, we eliminated those studies in which a well-defined E point could not be identified. The incidence of increased EPSS was equal in patients with and without fluttering. It is also possible that some of the patients with severe AR and normal EF had reduced LV contractility. In these patients, EF could seemingly have been preserved because of the independent influence of increased preload and ventricular dilatation. Cardiac output, however, does not appear to significantly influence EPSS in patients with AR.

Impingement of the aortic jet on the body of the anterior mitral leaflet appears to cause the leaflet to bow away from the septum as the valve opens.[7] This is likely to account for observations of abnormal EPSS in patients with normal EF.

In conclusion, EPSS is not a useful predictor of LV function or dilatation in individual patients with AR, although greater EPSS tends to be seen in those patients with larger left ventricles and reduced EF.

Auscultation, M-Mode Echocardiography and Pulsed Doppler Echocardiography Compared with Angiography for Diagnosis of Chronic Aortic Regurgitation

DAVID G. MEYERS, MD
TERRY S. OLSON, BS
DALE A. HANSEN, MD

Pulsed Doppler echocardiography (PDE), which detects velocity, timing and direction of blood flow, is both sensitive and specific in detecting aortic regurgitation (AR) and appears to be superior to more standard noninvasive techniques.[1] In our study, 3 noninvasive means of detecting AR—cardiac auscultation, M-mode echocardiography (echo) and PDE—were compared with aortography.

From the University of Nebraska Medical Center, Section of Adult Cardiology, 42nd and Dewey Avenue, Omaha, Nebraska 68105. Manuscript received March 28, 1985; revised manuscript received May 7, 1985, accepted May 8, 1985.

Twenty patients (9 men, 11 women, aged 27 to 76 years) underwent cardiac catheterization for evaluation of either mitral or aortic valve disease. Aortograms were reviewed by an investigator blinded to the results of noninvasive studies, who estimated AR severity using the technique of Grossman and Dexter.[2] Echocardiographic and PDE studies were usually performed before angiography (27 ± 30 days, range 2 to 84) on a Honeywell Ultra-Imager duplex echocardiograph with transducer frequencies of 2.5, 3.5 and 5.0 MHz by technicians blinded to the results of auscultation and angiography. No attempts were made to control ventricular loading conditions. M-mode echocardiograms were recorded at a scan speed of 50 mm/s from the standard parasternal position. Pulsed Doppler echocardiograms were recorded from 3 standard positions (parasternal long axis, apical 4-chamber and apical long axis) with the Doppler sampling site positioned in the left ventricular outflow tract just below the aortic valve under 2-dimensional echocardiographic guidance. The Doppler signal was recorded in both video and audio formats using a Honeywell VGR 4000 video graphics recorder.

An investigator blinded to the results of all other studies evaluated the echocardiographic and, separately, PDE results. AR was not quantitated. Two weeks later, the original reviewer and another investigator, blinded to prior interpretations, independently reviewed all PDE studies. The final PDE diagnosis was based on the consensus of these 3 independent interpretations. High-frequency diastolic fluttering of the mitral leaflets, chordae tendineae, or left

Echo = M-mode echocardiography; FN = false negative; FP = false positive; PDE = pulsed Doppler echocardiography; TN = true-negative; TP = true positive.

ventricular surface of the ventricular septum served as the echocardiographic marker of AR. AR was diagnosed if PDE showed spectral broadening with a duration of longer than 0.10 second and a peak velocity of more than 20 cm/s, suggesting turbulent, apically directed, diastolic blood flow in the left ventricular outflow tract.

The sensitivity, specificity, predictive values and accuracy of the noninvasive techniques were calculated relative to angiography (Table I). AR was detected angiographically in 11 patients; it was mild (1 to 2+) in 8 patients and moderate (3+) in 3. M-mode echocardiograms were recorded in 17 patients. Of the 8 patients with mild AR, auscultation detected AR in 3, M-mode echo detected it in 4 and PDE detected it in 7. In the 3 patients with moderate (3+) AR, both PDE and auscultation were 100% sensitive. M-mode echo failed to detect AR in 2 of these patients, both of whom had mitral stenosis. Doppler interpretation was based on only 1 transducer position in 11 patients and 2 positions in 5. Both inter- and intraobserver variation with PDE were 5%.

Auscultation produced 5 false-negative studies, 4 of which occurred in patients with mild AR. Of the 5 false-negative echocardiographic studies, 4 occurred in patients with mitral stenosis and 1 in a patient with mild AR. Only 1 false-negative diagnosis resulted from PDE, in a patient with mild, isolated AR. There were no false positive results from any method.

Our data, like those of Saal et al,[1] show that neither cardiac auscultation nor M-mode echo is sensitive for detecting AR (especially when mild) in contrast to PDE. In studies comparing auscultation and M-mode echo,[1,3] both had sensitivity of less than 80%, whereas in noncomparative studies, PDE had a sensitivity of 92 to 100%.[4,5] The low sensitivity of auscultation may stem, in part, from the difficulty in appreciating the faint, high-pitched murmur when AR is mild or, to a lesser extent, in the presence of the murmur of mitral stenosis. Similarly, the low sensitivity of M-mode echo may be largely attributed to mitral stenosis where leaflet thickening dampens diastolic leaflet flutter.[3,6] Either mild AR or mitral stenosis account for all the false-negative studies with auscultation and echo in our series. Our experience confirms that PDE is superior to both auscultation and M-mode echo in detecting AR (especially mild AR) and is not limited by mitral stenosis.

Left Atrial Mobile Thrombus in Hypertrophic Cardiomyopathy

MAREOMI HAMADA, MD
WATARU MATSUBARA, MD
NAOAKI TOMITA, MD
YUSUKE MIYAUCHI, MD
TATSUO KOKUBU, MD

From the Second Department of Internal Medicine, Ehime University School of Medicine, Shigenobu-cho, Onsen-gun, Ehime 791-02, Japan.

Manuscript received March 15, 1985; revised manuscript received May 10, 1985, accepted May 13, 1985.

Atrial fibrillation (AF) and low cardiac output are closely related to the occurrence and development of left atrial (LA) thrombi. Some investigators[1–3] reported that AF was observed in 5 to 15% of patients with hypertrophic cardiomyopathy (HC). Henry et al[4] reported that AF was observed in more than 40% of patients with asymmetric septal hypertrophy and LA dimension of 40 mm or greater. To our knowledge, however, no patient has been described with HC who had a LA mobile thrombus. We present 2 such patients.

Case 1: *A 52-year-old man treated for HC was admitted 2 days after sudden onset of palpitation and chest discomfort. The blood pressure was 94/76 mm Hg. An electrocardiogram revealed AF with high R voltages and negative T waves*

in the precordial leads. After 3 days of hospitalization, AF returned to sinus rhythm with disopyramide therapy and bed rest. Two-dimensional echocardiograms (Fig. 1) revealed LA mobile thrombus occurring in the vicinity of the LA appendage. An echocardiogram recorded 3 months before admission showed a marked increase in ventricular septal thickness but did not show a thrombus. Cardiac index, measured by the dye-dilution method, was 2.3 liters/min/m^2 (Table I).

Case 2: *A 49-year-old man with a history of recurrent faintness was admitted complaining of palpitation and general malaise. The blood pressure was 92/70 mm Hg. An*

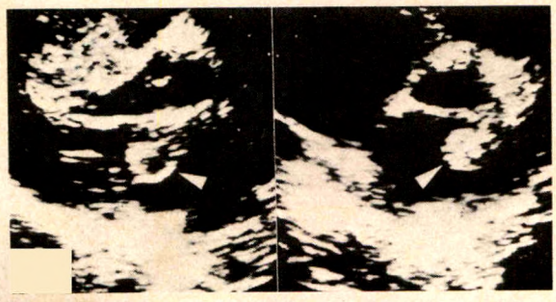

FIGURE 1. Long-axis (**left**) and short-axis (**right**) 2-dimensional echocardiograms from patient 1. A mobile thrombus (**arrow**) was observed in the left atrial cavity. During the cardiac cycle, the thrombus was most clearly observed from late diastole to early systole (**left**). From the short-axis echocardiographic observation, the thrombus was seen to occur in the vicinity of the left atrial appendage (**right**).

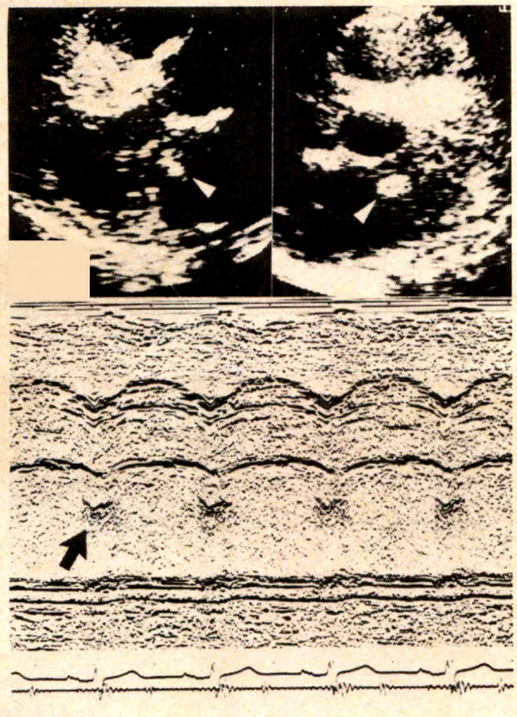

FIGURE 2. Two-dimensional and M-mode echocardiograms from patient 2. In the long-axis 2-dimensional echocardiogram, a thrombus was most clearly observed at early systole (**top, left**). From the short-axis echocardiographic observation (**top, right**), the thrombus occurred in the vicinity of the left atrial appendage as seen in patient 1. In the M-mode echocardiogram (**bottom**), the thrombus (**arrow**) was also recognized from end-diastole to early systole in the left atrial cavity.

TABLE I Hemodynamic and Echocardiographic Measurements

Pt	HR (beats/min)	SBP/DBP (mm Hg)	CI (liters/min/m^2)	SI (ml/beat/m^2)	TPRI (dynes s cm^5)	LVDd (mm)	LVDs (mm)	LAD (mm)	VS (mm)	PWT (mm)	VS/PWT	SAM	MSC
1	58	100/68	2.3	40	2,745	42	29	41	22	10	2.2	+	+
2	52	116/70	1.9	37	3,575	38	25	44	29	14	2.1	–	+

CI = cardiac index; HR = heart rate; LAD = left atrial dimension; LVDd = left ventricular end-diastolic dimension; LVDs = left ventricular end-systolic dimension; MSC = midsystolic closure of the aortic valve; PWT = left ventricular posterior wall thickness; SAM = systolic anterior motion of the mitral valve; SBP/DBP = systolic/diastolic blood pressure; SI = stroke index; VS = ventricular septal thickness; + = present; – = absent.

electrocardiogram showed AF with negative T waves in leads V_5, V_6, I and aVL. After 5 days of the hospitalization, AF returned to sinus rhythm, but soon after he complained of severe ache in his left leg owing to embolic complication. Echocardiograms showed marked ventricular septal thickening and a mobile thrombus occurring in the vicinity of the LA appendage (Fig. 2). The patient showed not only reduced cardiac index, but also markedly elevated total peripheral resistance index (Table I).

During the cardiac cycle, the thrombi observed in 2 patients showed the same pattern of motion that was observed most clearly from end-diastole to early systole. Emergency cardiac surgery was performed in both patients and thrombi were removed. In addition, to prevent formation of the LA thrombus, plication of the LA appendage was performed. Diastolic compliance failure of HC appeared to be the main cause of AF. The combination of stagnant blood flow due to AF and low cardiac output appeared to predispose to thrombus formation.

Acknowledgment: We thank Yo Osuga, MD, for performing the corrective surgery.

Acute Left Ventricular Dysfunction and Thrombosis Following Natural Gas Poisoning

RAYMOND P. KELLY, MB BS (Hons)
DWAIN A. OWENSBY, MD, PhD, FRACP

Left ventricular (LV) thrombus formation is a recognized complication of myocardial infarction[1] and of dilated cardiomyopathy,[2] but to our knowledge, it has not previously been reported in association with hypoxia-related reversible LV dysfunction. We describe such a case.

A 19-year-old woman was admitted to the hospital after accidental gas poisoning over approximately 12 hours. Initial resuscitation with oxygen reversed deep cyanosis and improved mental state from coma to stupor. The blood pressure was 90/60 mm Hg, heart rate 140 beats/min, respiratory rate 40 breaths/min and temperature 38.5°C. The patient weighed 50 kg. She was mildly dehydrated and had a prominent gallop rhythm. Arterial blood gases after initial resuscitation showed hypoxia (PO_2 55 mm Hg with oxygen 40%) and mild metabolic acidosis (pH 7.36, bicarbonate 14 mmol/liter). Carboxyhemoglobin was mildly elevated at 12.7% (normal 0 to 1.5%, with cerebral symptoms evident above 30%). Chest x-ray showed normal heart size and clear lung fields. An electrocardiogram showed sinus tachycardia.

The clinical course was one of progressive improvement of mental status with supplemental oxygen, intravenous rehydration, dexamethasone, 16 mg, amoxicillin and chest physiotherapy. Despite resolution of fever, the gallop rhythm and a tachycardia of 120 beats/min persisted at the end of 24 hours. Blood and urine cultures were sterile. Creatine kinase-MB fraction was not elevated, but an electrocardiogram showed widespread nonspecific ST-T changes with T-wave flattening. An echocardiogram was performed within 24 hours of admission. The left ventricle was mildly dilated (end-systolic diameter 40 mm [normal 28 ± 6 mm], end-diastolic diameter 51 mm [normal 44 ± 6 mm]) with reduced fractional shortening (22% [normal 26%]). All valves appeared intrinsically normal, but interrupted aortic valve closure and a "B" notch on the mitral valve trace were consistent with elevated LV end-diastolic pressure. The 2-dimensional echocardiogram also confirmed mild global cardiac enlargement and reduced contraction with an ejection fraction of 40% (based on single-plane ellipsoid formula for LV volume). Within 4 days, mental function had returned to normal, the gallop rhythm was absent and tachycardia resolved to an awake heart rate at rest of 80 beats/min. A repeat echocardiogram 4 days later showed normalization of LV dimensions (end-systolic diameter 30 mm, end-diastolic diameter 47 mm) and fractional shortening (36%). On the 2-dimensional sector scan, ventricular size and function appeared normal but an apical thrombus measuring 10 mm in diameter was clearly demonstrated in multiple views and at various depth and gain settings (Fig. 1).

The 2 most striking aspects of this case are the prompt resolution of the initial clinical and echocardiographic features of severe myocardial dysfunction, and the unexpected discovery of an apical LV thrombus on the predischarge echocardiogram. The speed of recovery of myocardial function suggests that no significant intrinsic myocardial damage was sustained but rather that a "stunned" myocardium[3] was responsible for the reversible dysfunction. The constituents of

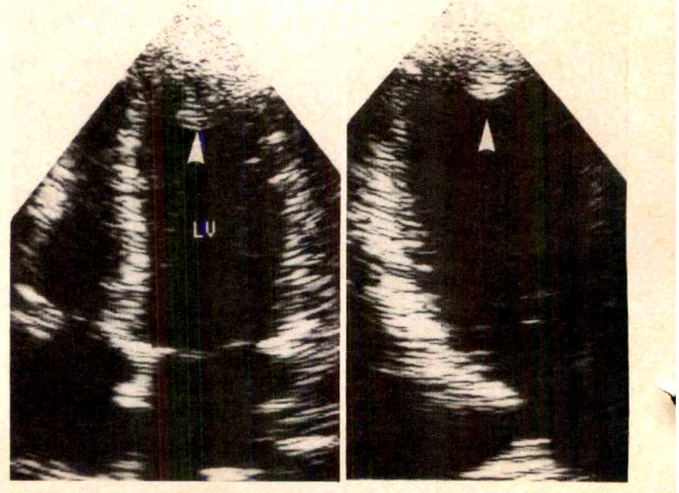

FIGURE 1. Left, apical 4-chamber view demonstrating thrombus (**arrow**) in left ventricular (LV) apex. **Right,** apical 2-chamber view demonstrating LV thombus (**arrow**).

natural gas (predominantly methane, and small to trace amounts of other hydrocarbons, nitrogen, carbon dioxide and mercapto compounds) are not known to have direct myocardial toxicity[4] in the concentrations encountered; thus, hypoxia rather than toxicity must be considered the responsible mechanism.[5]

The hypoxic myocardial dysfunction in this patient was completely reversible, although in the interim an LV thrombus had formed rapidly and thus may complicate any form of acute cardiomyopathy.

Massive Endocardial Calcification Associated with Endomyocardial Fibrosis

MARIA LENGYEL, MD
ATTILA ÁRVAY, MD
IMRE PALIK, MD

Silver et al[1] described massive mural calcific deposits as a newly recognized cause of impairment to left ventricular filling. We present 2 patients with massive endocardial calcification who also had typical features of nontropical endomyocardial fibrosis (EMF).

Patient 1: *A 53-year-old woman had bronchial asthma since early childhood. Six months before admission atrial fibrillation developed with severe exertional and nocturnal dyspnea and a 3/6 holosystolic apical murmur. Chest x-ray showed a conspicuous calcification (Fig. 1.). Two-dimensional echocardiography (2-D echo) revealed massive calcification on the endocardium at the left ventricular apex, the distal third of the septum and the posterior wall and on both papillary muscles. Cardiac catheterization and angiography disclosed a typical "ace of hearts"–shaped left ventricle massive mitral regurgitation and elevated (22 mm Hg) left ventricular end-diastolic and pulmonary artery pressure (62/30 mm Hg) (Fig. 2.). At surgery, masses of friable and partly calcified thrombi and parts of the calcified endocardium were removed (Fig. 3), and the mitral valve was replaced. Cardiac catheterization 6 months postoperatively revealed a left ventricular end-diastolic pressure of 11 mm Hg and pulmonary arterial pressure of 37/17 mm Hg.*

Patient 2: *A 42-year-old woman with a history of helminthiasis was studied because of progressive dyspnea. Two-dimensional echo showed massive calcification of the left ventricular endocardium primarily at the region of the apex and the septum, an obliterated right ventricular apex and dilated atria (Fig. 4). Cardiac catheterization and angiography revealed elevated left and right ventricular end-diastolic pressures, mild tricuspid regurgitation and right ventricular apical obliteration. Over a follow-up period of 1 year, medical treatment has kept this patient in functional class II.*

We have seen 9 patients with eosinophilic EMF with or without eosinophilia over the last 6 years, and 8 of them underwent operation. The 2 patients just described had characteristic clinical, 2-D echo, hemodynamic and angiographic signs of EMF without eosino-

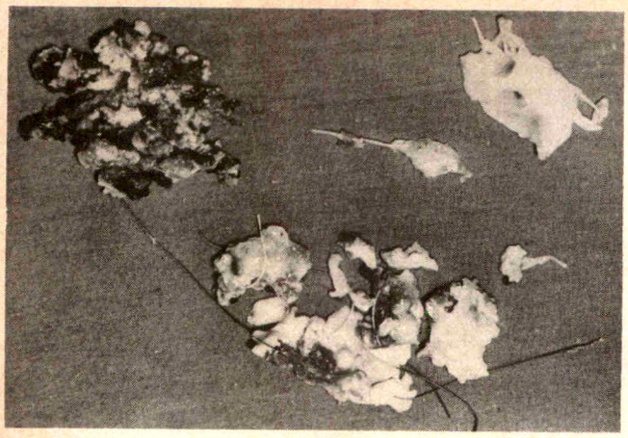

FIGURE 3. Masses of calcified and friable thrombi, calcified endocardium and a pliable mitral leaftlet removed at surgery from patient 1.

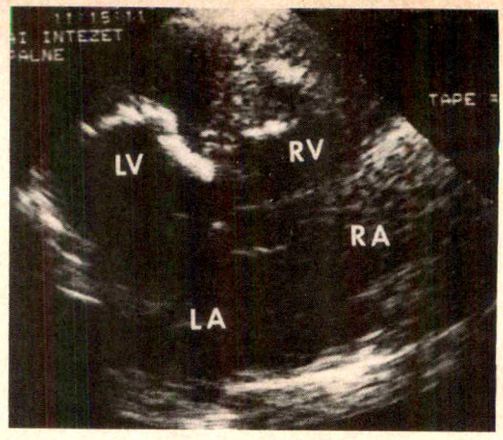

FIGURE 4. Two-dimensional echocardiogram obtained in the apical 4-chamber view in patient 2. There is massive calcification of the septum of the left ventricular apex and, to a lesser degree, of the right ventricular apex. Both atria are dilated. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

philia. Patient 1 also had morphologic signs of EMF without eosinophilia. They may have had eosinophilia in the earlier course of their disease, associated with parasitic infection in 1 patient and asthma in the other. In addition, they had massive calcification of the endocardium of the left ventricle. Our observations thus do not seem to support the view that massive calcification represents an entity independent of EMF.[1] On the contrary, these 2 cases confirm previous observations and support the opinion that extensive, widely distributed calcific deposits may be present within the left ventricular cavity in patients with EMF.[2–6] Endocardial calcification in these cases may be the diagnostic clue calling attention to the probable presence of EMF.

Effect of Intense Aerobic Training on Exercise Performance in Children After Surgical Repair of Tetralogy of Fallot or Complete Transposition of the Great Arteries

LINDA M. BRADLEY, MD
FRANK M. GALIOTO, Jr., MD
PAUL VACCARO, PhD
DENISE A. HANSEN, BS
JANE VACCARO, MS

The role of rehabilitation after surgical repair of cyanotic congenital heart defects in children is unclear. Although highly effective cardiac rehabilitation programs exist for adults with acquired cardiac disease, few are available for children.[1,2] Hemodynamic and electrophysiologic disturbances are often present after surgical repair of congenital heart lesions. Diminished right and left ventricular compliance[3] and late dysrhythmias[4] are seen after the Mustard operation for complete transposition of the great arteries (TGA). Patients with repaired tetralogy of Fallot (TF) may have abnormal right and left ventricular function[5] and ventricular arrhythmias.[6,7] Further, exercise capacity is known to be subnormal in children following repair of TGA[3] and TF.[8] We report the effects of a monitored aerobic training program on children who had undergone operative repair of TGA or TF to determine the magnitude of potential improvement in aerobic fitness and to develop a scientific basis for rational exercise guidelines.

Eleven patients were selected for participation in the study because of the nature of their lesions and their proximity to the hospital. Nine of 11 patients completed the program and form the basis of this report (Table I). All 9 patients had undergone operative repair more than 2 years before the program began.

The 5 patients in the TGA group had undergone Mustard's operation 4 to 11 years earlier (mean 7.11) at a mean age of 10 months. Three of the 5 patients required subsequent pacemaker implantation for dysrhythmia management and 2 required digoxin and propranolol therapy. Postoperative cardiac catheterization data were available in 4 of 5 patients. All had a normal cardiac index at rest, normal right ventricular end-diastolic pressure and normal pulmonary vascular resistance. Angiographically, none had tricuspid

p	NS		NS		NS		<0.001		<0.01		<0.01	

BP = systolic blood pressure; HR = heart rate; NS = not significant; SEM = standard error of the mean; TT = treadmill time; $\dot{V}E$ = minute ventilation; $\dot{V}O_2$ = oxygen consumption.

regurgitation or subpulmonic obstruction, and 2 had slightly diminished right ventricular contractility.

The 4 patients with TF had undergone repair, 2 with a transanular right ventricular outflow tract patch, 2 to 8.5 years earlier (mean 4.4) at a mean age of 39 months. One patient required reoperation for residual right ventricular outflow tract obstruction and pacemaker placement. Follow-up catheterization data were available in 3 patients. All patients had a normal cardiac index at rest, normal right and left ventricular end-diastolic pressures, and mildly elevated right ventricular systolic pressure (Table I). Angiographically, all had qualitatively normal right and left ventricular contractility. One patient each had mild, moderate and severe pulmonary insufficiency. All 4 patients had right bundle branch block.

Graded treadmill tests were conducted before and after 12 weeks of aerobic training. Tests were performed on a motor-driven treadmill (model 18-54, Quinton Instruments) while an electrocardiogram, cuff blood pressure and intermittent oxygen consumption were monitored. A modified Bruce protocol was used. Subjects were fitted with a mouthpiece containing a 2-way valve and a pneumotachograph (Fleish type, Dynasciences). Expired air was analyzed for oxygen and carbon dioxide content (Perkin-Elmer 1100 Medical gas analyzer). The outputs were sampled every 2 minutes for 30 seconds by a microcomputer (NOVA 3, Data General) programmed to assess and print minute ventilation, oxygen consumption and respiratory quotient. The subjects were encouraged to continue as long as possible to obtain maximal treadmill times. All tests were terminated owing to fatigue.

Training sessions were held in the gymnasium at Children's Hospital National Medical Center twice a week for 12 weeks. Each class was directed by an elementary physical education specialist with an exercise physiologist and pediatric cardiologist present. A portable defibrillator and an emergency medical cart were available in the room. Each class commenced with a 15-minute warm up period of stretching and flexibility exercises. Aerobic activities such as walking, running, jumping rope and modified aerobic dance followed the warm-up period and lasted 15 to 30 minutes. Workloads of 60%, 70% and 80% of maximal heart rate were achieved. Each session concluded with a 15 minute cool-down period to prevent venous pooling in the extremities. Rest, peak exercise and recovery single-lead electrocardiograms were recorded in all patients at each session with a portable device (MSG-IM Schiller). Starting in the sixth week of the program, all patients were instructed to spend at least 25 to 35 minutes once a week in home-based, family-oriented aerobic exercise (i.e., brisk walking or jogging).

Data analyzed for statistical significance included weight, heart rate, minute ventilation, peak systolic blood pressure, treadmill time and oxygen consumption. Measurements before and after training were compared by a Student paired t test. A p value <0.05 was considered significant. Electrocardiographic tracings were reviewed for rhythm disturbances and ST-T-wave changes.

Table II contains the exercise data of each patient before and after completion of the cardiac rehabilitation program. Maximal values are listed. Weight, heart rate and minute ventilation did not change significantly during the study

interval. Peak systolic blood pressure increased 17% (from 116 to 140 mm Hg, $p < 0.001$), treadmill time increased 18% (from 11.7 to 14.2 minutes, $p < 0.01$) and oxygen consumption increased 20% (from 37 to 45 ml/kg/min, $p < 0.01$). Treadmill electrocardiograms before and after the cardiac rehabilitation program did not document significant ST depression at peak exercise in any patient. Three of the 4 children with pacemakers had paced rhythm at rest; all 3 demonstrated sinus rhythm with peak exercise. There were no complications.

Conditioning programs for normal children have variable design, duration and intensity and produce improved levels of aerobic fitness as measured by maximal work capacity or maximal oxygen consumption.[2,9] The cardiopulmonary alterations that occur in normal school-aged children after a season of competitive swimming have been documented.[10] Only Goldberg et al[1] and Ruttenberg et al[2] studied the effects of exercise training on children after cardiac surgery. In the former study, a significant improvement in maximal work capacity occurred in patients with postoperative TF and ventricular septal defect. Maximal oxygen consumption did not significantly increase. Similarly, the study by Ruttenberg et al revealed significant improvement in maximal treadmill performance (time and stage) in patients with postoperative TF, aortic stenosis, TGA and arterioventricular canal, although maximal oxygen consumption did not change.

This study differs from those previously reported. The patients are younger than those studied by Goldberg and Ruttenberg and their co-workers and have more severe residual disease. Sixty percent of the study patients with TGA are pacemaker-dependent at rest. The mean systolic gradient across the right ventricular outflow tract in the TF group is 20 mm Hg. The duration of the training program is longer than that in either of the previous 2 studies. Because the program is hospital-based, electrocardiographic monitoring is possible. We confirmed that all participants exercised to achieve and maintain heart rates of 60 to 80% of maximum heart rate, which constitutes more intense exertion than in the study of Goldberg et al.

The current results, however, agree with those previously published. After training, heart rate and minute ventilation did not significantly change. Both peak systolic blood pressure and treadmill time improved substantially. In our patients maximal oxygen consumption also increased significantly, a result we attribute to the documented major increase in intensity and duration of our rehabilitation program.

A monitored pediatric cardiac rehabilitation program can improve the aerobic fitness of young children, even in the presence of moderate hemodynamic or electrophysiologic disturbance.

Acknowledgment: We thank Joann Duck for her dedicated assistance in manuscript preparation.

Coarctation of the Aorta Inherited as an Autosomal Dominant Trait

ROBERT H. BEEKMAN, MD
MEINHARD ROBINOW, MD

Coarctation of the aorta (CoA) usually occurs sporadically.[1,2] Familial recurrence of CoA has been reported in sibling and parent-child groups, however, in patterns compatible with multifactorial inheritance.[2,3] In this report we describe a family in which CoA affected 4 generations in a pattern consistent with autosomal dominant inheritance. This is the first reported instance of CoA inherited in classic Mendelian fashion.

From the Divisions of Cardiology and Genetics, Department of Pediatrics, The Children's Medical Center, Wright State University School of Medicine, Dayton, Ohio. Dr. Beekman's present address: Division of Pediatric Cardiology, Box 66, C. S. Mott Children's Hospital, Ann Arbor, Michigan 48109. Manuscript received April 15, 1985; revised manuscript received May 6, 1985, accepted May 7, 1985.

***Case 1* (*IV 1, Fig. 1*):** *The index case presented at age 1 year for evaluation of a heart murmur. He was asymptomatic. Systolic blood pressure (Doppler) was 122 mm Hg in the right arm and 110 mm Hg in the legs. A grade 2/6 systolic ejection murmur was heard in the back. Cardiac catheterization revealed mild thoracic CoA, with a systolic gradient at rest of 10 mm Hg. No other cardiovascular abnormalities were present.*

***Case 2* (*III 7, Fig. 1*):** *This 29-year-old woman, in excellent health, was evaluated because of the striking family history of CoA. Her physical examination was unremarkable. Blood pressures at rest were 131/85 mm Hg in both arms and 132 mm Hg in the leg. A graded exercise test was performed in an attempt to elicit evidence of a subclinical CoA. Although no pressure gradient was present between arm and leg at rest, a 46-mm Hg systolic gradient was measured on multiple recordings immediately after peak exercise. Typical postexercise pressures were 148/50 mm Hg in the right arm and 102 mm Hg in the leg. An aortogram failed to document a CoA. No pressure gradient at rest was detected within any portion of the aorta.*

***Case 3* (*II 3, Fig. 1*):** *At age 15 years the patient had a blood pressure of 240/100 mm Hg in the right arm and 120/80 mm Hg in the leg. Murmurs consistent with aortic stenosis*

and insufficiency were present. A chest radiograph showed severe cardiac enlargement and rib notching. Surgical repair of the CoA was performed by excision and end-to-end anastomosis. Although the pressure gradient at rest was abolished, persistent hypertension and aortic insufficiency led to the patient's death 7 years later at age 22 years.

Case 4 (II 2, Fig. 1): *The patient developed hypertension, dyspnea on exertion and frequent headaches in her teens. At age 28 years, after 3 syncopal episodes, she was found to have a blood pressure of 200/120 mm Hg in the arms and diminished femoral pulses. At surgery, a tight thoracic CoA was repaired by excision and end-to-end anastomosis. On the first postoperative day the patient had a cardiac arrest and died.*

Case 5 (I 1, Fig. 1): *Upper extremity hypertension was first discovered when this women was 25 years old. She was treated medically and followed a satisfactory course until age 68 years, when she was hospitalized with chest pain and supraventricular tachycardia. Blood pressure was 220/120 mm Hg in the arms and 90 mm Hg in the legs. Soon after admission ventricular fibrillation developed and she died. Necropsy revealed severe thoracic CoA and multiple large collateral vessels.*

Other relatives: *No other members of the family have been studied. Members I 1 and I 2 (Fig. 1) are in good health in their late 70s and are presumably unaffected.*

Familial coarctation of the aorta is rare.[1,2] Only 26 families have been reported previously in which CoA occurred in more than 1 member.[1–5] In no family has CoA affected more than 2 generations, and in no instance has a pattern of Mendelian inheritance appeared. Familial CoA, as with most other types of congenital heart disease, has been attributed to multifactorial causation.[2,3] In the present report a family is described in which CoA appears to have been transmitted as an autosomal dominant trait with high penetrance and variable expressivity. Five family members in 4 generations have been affected, some with severe and others with mild CoA. (X-linked dominant inheritance cannot be ruled out because there has been no male-to-male transmission.) Case 2 appears to be a carrier, since her aorta was not grossly abnormal by angiography. The exercise-induced pressure gradient in this patient is difficult to explain, however, as one does not occur in normal persons.[6] It is tempting to speculate that this patient has a minimal expression of the trait in which a segment of aorta, although not anatomically narrowed, lacks the compliance to dilate normally during exercise.

The concept that genetic factors influence the development of CoA in some patients is not new. It is well known, for instance, that CoA occurs commonly in patients with XO Turner syndrome. Classic Mendelian inheritance of CoA, however, has not been previously documented. In this report we have described a family in which CoA was traced through 4 generations in a pattern consistent with autosomal dominant inheritance.

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work may also be submitted.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript, including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article; (3) miniabstract for Table of Contents that includes the full title and names of all authors; (4) abstract; (5) text; (6) references; (7) acknowledgment; (8) figure legends; and (9) tables. Number all pages in the above sequence, beginning with the title page as 1, the abstract as 2, and so on. (Leave the second title page and the miniabstract unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references), with at least 25-mm (1-inch) margins.

The second title page, on which the names and institution of the authors are omitted, gives the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is always honored.

TITLE PAGE, TABLE OF CONTENTS ABSTRACT AND MINIABSTRACT: For the **complete title page,** include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code.

Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 4 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage.

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

FIGURES: Submit 3 glossy, unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present," a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no."

BRIEF REPORTS: Brief Reports must be limited to no more than 3 text pages and 6 references. Longer ones usually will be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used in the body of the Brief Report.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor-in-Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

Transderm-Nitro®

(nitroglycerin)
Transdermal Therapeutic System

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.
In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.
Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.
Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.
The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone.
The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.
Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

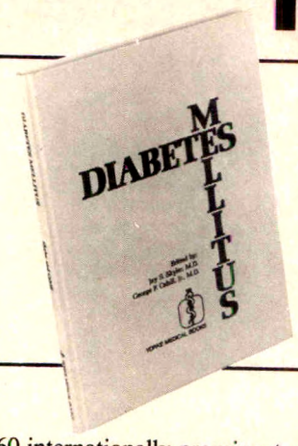
DIABETES MELLITUS



From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes.

Featured topics include:

- ☐ The causes of diabetic inheritance
- ☐ Immune factors of diabetes
- ☐ Mechanisms of diabetes (The culmination of 50 years of research)
- ☐ Autoimmunity
- ☐ New understandings in the mechanisms of insulin dependent and non-dependent diabetes mellitus
- ☐ New developments in the treatment of diabetes
- ☐ Methods of monitoring blood glucose and the use of glycosylated hemoglobin
- ☐ Pharmacology of oral hypoglycemics
- ☐ Use of insulin infusion devices
- ☐ Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

CONTROL. EVERY STEP OF THE WAY.

Introducing HEART-TRAK™ PTCA Catheter with the exclusive high-strength CLE™ Balloon, specially designed to provide precise control... from insertion, to inflation, to withdrawal.

Even at maximum inflation pressures, our CONTROLLED LINEAR EXPANSION process assures a polyethylene balloon of maximum strength which consistently maintains its shape for a safe and effective dilatation.

Its construction assures accurately controlled high pressure inflation with non-compliant symmetry and minimal distensibility ...with the most consistently predictable balloon sizing of any balloon available. Even after repeated inflations.

During insertion our specially treated polyethylene catheter provides the right combination of flexibility, smoothness, push force and trackability—allowing HEART-TRAK to easily negotiate tortuous vessels and sharp angulations. During inflation, our balloon gives you the confidence that the vessel will be dilated effectively and safely.

HEART-TRAK™ PTCA CATHETER

Confidence in the most critical cases

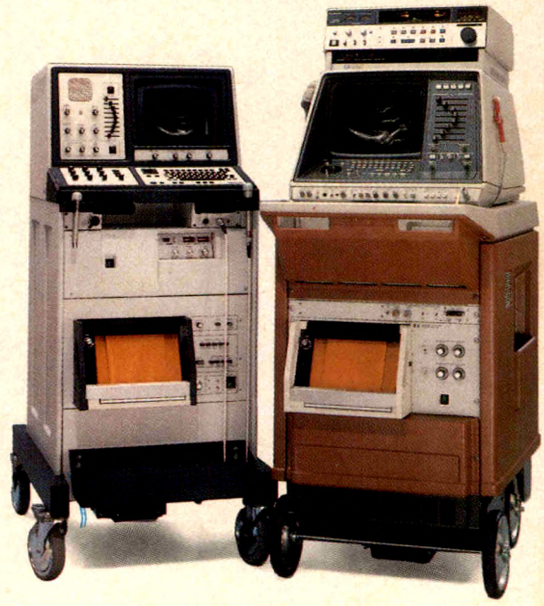
In most cases, our field service engineers are never more than 50 miles away.

There are still a few places an HP field service engineer can't reach in an hour. So when NASA chose the **Hewlett-Packard ultrasound** imaging system for Spacelab 4, they chose it for its reliability. You don't get second chances when you're hundreds of miles from earth.

Reliability. Hewlett-Packard's pretesting practically guarantees it. Our tests exceed even the toughest NASA requirements. And HP ultrasound's remote diagnostic capabilities and self-testing features make system evaluation simple, comprehensive and dependable. Our track record here on earth proves it—99% average uptime in existing hospital installations.

Your ultrasound system will never have to survive launch, orbit and reentry. But it will have to survive the even tougher tests of cost-effectiveness, upgradeability, image quality and long-term reliability. Achieving all this may seem an astronomical task for some. For HP, the achievement is a fact of life.

To find out more about the complete line of Hewlett-Packard ultrasound imaging systems, write to: Inquiries Manager, Hewlett-Packard, Dept. A18, 3000 Minuteman Road, Andover, MA 01810. Or call your local HP sales office listed in the White Pages.



Hewlett-Packard offers two superior cardiac imaging systems with Doppler capabilities: the HP77020AC phased array imaging system and the HP77065AC mechanical imaging system. Both provide incomparable image quality and reliability.

HEWLETT PACKARD

BEHIND THE FACE OF HYPERTENSION

New evidence for central control

For the elderly hypertensive

"...with increasing age, norepinephrine response to posture and exercise increases..."[1]

Effective central control of blood pressure

Tablets of 0.1, 0.2, 0.3 mg

Catapres®

(clonidine HCl)

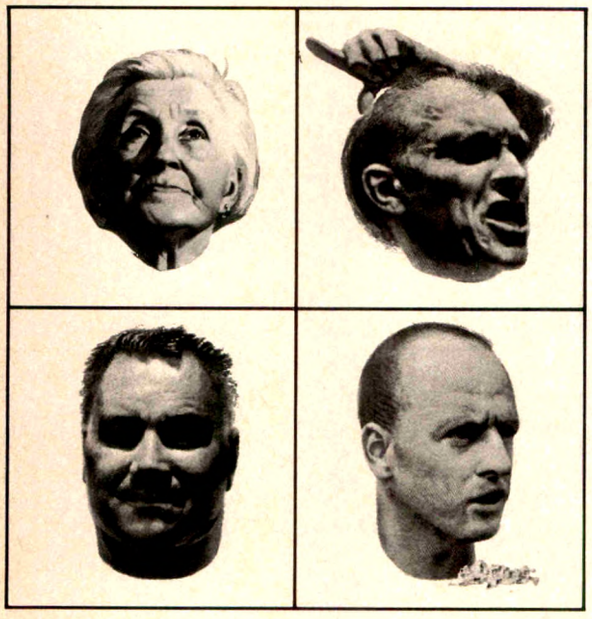
Hypertension

Please see last page for brief summary, including warnings, precautions, and adverse reactions.

BEHIND THE FACE OF HYPERTENSION

New evidence for central control

Catapres®
(clonidine HCl)
Hypertension



Catapres®

(clonidine hydrochloride)

Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 and unit dose package of 100. Also available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.

THE QUINTON 3000 SYSTEM IS SO VERSATILE, IT CAN SUPPORT ITSELF.

Quinton
instrument co.

With the Quinton 3000 System, you'll never again leave your office when a patient needs a comprehensive stress test.

The Quinton 3000 System is easy to operate, and gives you more information, more accurately, than any other office stress testing equipment you can buy. In addition, you get it all at a better price—a price so good, in fact, that with two to three stress tests per month the system will pay for itself. Send us the coupon or call, toll-free, **800-426-0347** to see what words alone cannot express. We'll show you just how much the Quinton 3000 System can do for you. In Washington and Canada, Call **206-223-7373.**

London: A.H. Robins Medical Instruments Division, Mountcliff House 154 Brent Street, Hendon, London, N.W. 4, England

☐ I'm interested in a stress-test system that can support itself.

WHEN YOUR
PATIENT IS TRAPPED
BY ANGINA
AND THE FEAR
OF THE NEXT
ATTACK...

CORGARD® (nadolol tablets)

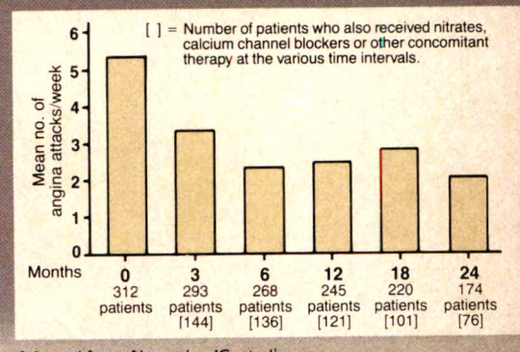
SQUIBB®

PROTECTS AGAINST ANGINA BREAK THROUGH*

*The syndrome of recurring symptoms compounded by the fear of impending attacks.

REDUCES ANGINA ATTACKS

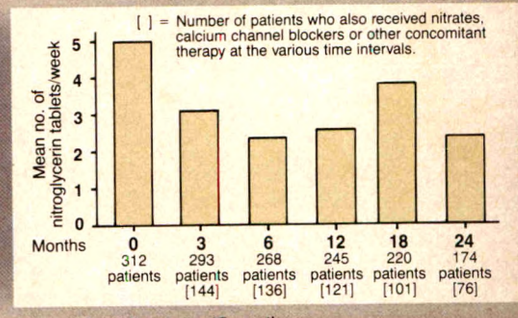
In a two-year study, CORGARD reduced the frequency of attacks from 5.3 per week to 2.1.[1]



Adapted from Alexander JC, et al[1]

REDUCES NITRO-GLYCERIN NEED

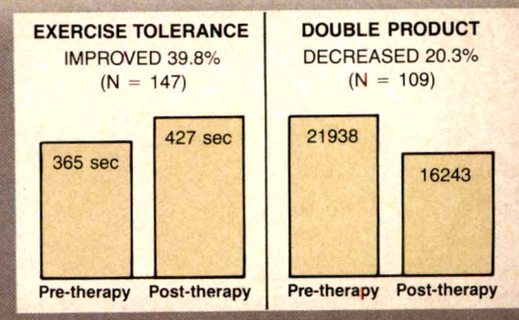
Nitroglycerin requirements were less than half by the end of the two-year clinical study. The average nitroglycerin consumption was reduced to 2.3 tablets per week.[1]



Adapted from Alexander JC, et al[1]

IMPROVES EXERCISE TOLERANCE

CORGARD significantly increases the patient's ability to participate in physical activity.[2]



References: 1. Alexander JC, et al: Long-term experience with nadolol in treatment of hypertension and angina pectoris. Am Heart J 108:1136-1140, 1984. 2. Data on file, Squibb Institute for Medical Research.

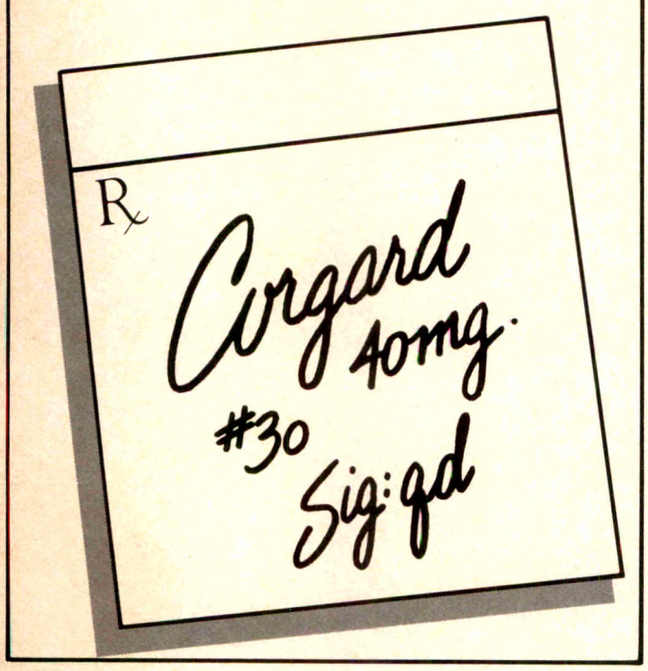
CORGARD®
(nadolol tablets)
R_x for Angina



CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery—Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia—Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis—Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Renal Function—Use nadolol with caution (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients—Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign of impending failure. Advise patients in event of missed doses.

Drug Interactions—Concurrent administration may result in interactions with: Anesthetics, general—exaggeration of the hypotension induced by general anesthetics (see WARNINGS, Major Surgery). Antidiabetic drugs (oral agents and insulin)—hypoglycemia or hyperglycemia; adjust antidiabetic drug dosage accordingly (see WARNINGS, Diabetes and Hypoglycemia). Catecholamine-depleting drugs (e.g., reserpine)—additive effect; monitor closely for hypotension and/or excessive bradycardia.

Carcinogenesis, Mutagenesis, Impairment of Fertility—In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy—In animal reproduction studies with nadolol, evidence of embryo-and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus. Neonates of mothers who received nadolol at parturition have exhibited bradycardia, hypoglycemia and associated symptoms.

Nursing Mothers—Nadolol is excreted in human milk. Exercise caution when nadolol is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular—Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System**—Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory**—Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal**—Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous**—Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision; infrequent reversible alopecia. The following adverse reactions have been reported in patients taking nadolol and/or other beta-adrenergic blocking agents, but no causal relationship to nadolol has been established. **Central Nervous System**—reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal**—mesenteric arterial thrombosis; ischemic colitis; elevated liver enzymes. **Hematologic**—agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic**—fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous**—pemphigoid rash; hypertensive reaction in patients with pheochromocytoma; sleep disturbances; Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia—Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure—Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension—Administer vasopressors, e.g., epinephrine or levarterenol. (There *is* evidence that epinephrine may be the drug of choice.)

Bronchospasm—Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; may be gradually increased in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 40 or 80 mg q.d. (doses up to 160 or 240 mg daily may be needed). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 40 or 80 mg q.d. (doses up to 240 or 320 mg daily may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets.

References: 1. Alexander JC, et al: Long-term experience with nadolol in the treatment of hypertension and angina pectoris. Am Heart J October Supplement 108 (4):1136-1140, 1984. 2. Data on file, Squibb Institute for Medical Research.

Innovators in cardiovascular medicine

Two-Dimensional Echocardiographic Diagnosis of Total Anomalous Pulmonary Venous Connection Below the Diaphragm

PUI-KAN LIAO, MD
WEN-JEN SU, MD
JUI-SUNG HUNG, MD

In cyanotic neonates, the presence of total anomalous pulmonary venous connection (TAPVC) often mimics pulmonary parenchymal disease, persistent fetal circulation and many other forms of cyanotic congenital cardiac malformations. In the last group with cardiac malformations, abnormalities of great arteries and intracardiac structures are readily identified by 2-dimensional echocardiography (2-D echo). When 2-D echo with contrast medium reveals normal intracardiac anatomy and a right-to-left atrial or ductal shunt, differentiation of TAPVC from pulmonary parenchymal disease and persistent fetal circulation remains a problem. Although characteristic features of TAPVC in 2-D echo have been described, experience in application of this diagnostic tool to the infradiaphragmatic type of TAPVC is limited.[1–4] We report 2-D echocardiographic findings of 2 neonates with infradiaphragmatic TAPVC.

Two-dimensional echo was performed in 2 cyanotic neonates with respiratory distress, aged 33 days (patient 1) and 2 days (patient 2), respectively. The diagnosis of infradiaphragmatic TAPVC was confirmed by angiography and at operation in patient 1. Patient 2 died a few hours after the echocardiographic examination before cardiac catheterization was performed.

The patients were examined in the supine position with the transducer placed in the precordial, subcostal and suprasternal positions. Standard echocardiographic views as described by Tajik et al[5] were obtained to assess the cardiac chambers, septa, cardiac valves, great arteries, great veins and the abdominal visceral situs. A Hewlett-Packard phased-array ultrasound system and an Aloca SSD 710 mechanical sector scanner, both with a 5-MHz focused transducer, were used in each case, respectively.

Two-dimensional echo in both patients showed normal ventricular and great artery anatomy with dilated right-sided heart chambers and the main pulmonary artery. The pulmonary valve showed typical motion of pulmonary hypertension on the M-mode display. An ostium secundum–type atrial septal defect and large patent ductus arteriosus were demonstrated in each case. The most striking finding in these 2 patients consisted of an enormously dilated venous channel, which ran posteroanteriorly in the craniocaudal direction within the liver on the longitudinal cut of the upper abdomen (Fig. 1A and 2A). It could easily be distinguished from the descending abdominal aorta and the normal-sized inferior vena cava (Fig. 1B and 2B). On the short-axis cut of the upper abdomen, this abnormal venous channel was located anterior to the inferior vena cava and the descending aorta near the midline but slightly to the left or right of the spine (Fig. 1C and 2C). Multiple communication between the abnormal venous channel and the intrahepatic veins (presumably portal veins) was demonstrated. The abnormal vein showed no direct connection with the inferior vena cava.

Despite presence of a small pulmonary vein-like structure joining the left atrium near the atrial septum in the subcostal view, no other pulmonary veins could be found. In view of these findings, infradiaphragmatic TAPVC was diagnosed.

Diagnosis of TAPVC by 2-D echo depends on demonstration of absence of normal pulmonary venous connection to the left atrium, presence of a common pulmonary vein, and the exact mode of abnormal connection of the common pulmonary vein.[1–4] In each of our patients, the diagnosis of infradiaphragmatic TAPVC was made because these criteria were satisfied.

From the Department of Pediatrics and the Department of Medicine, Chang Gung Memorial Hospital, 199 Tung Hwa North Road, Taipei 105, Taiwan, Republic of China. Manuscript received March 19, 1985; revised manuscript received May 6, 1985, accepted May 7, 1985.

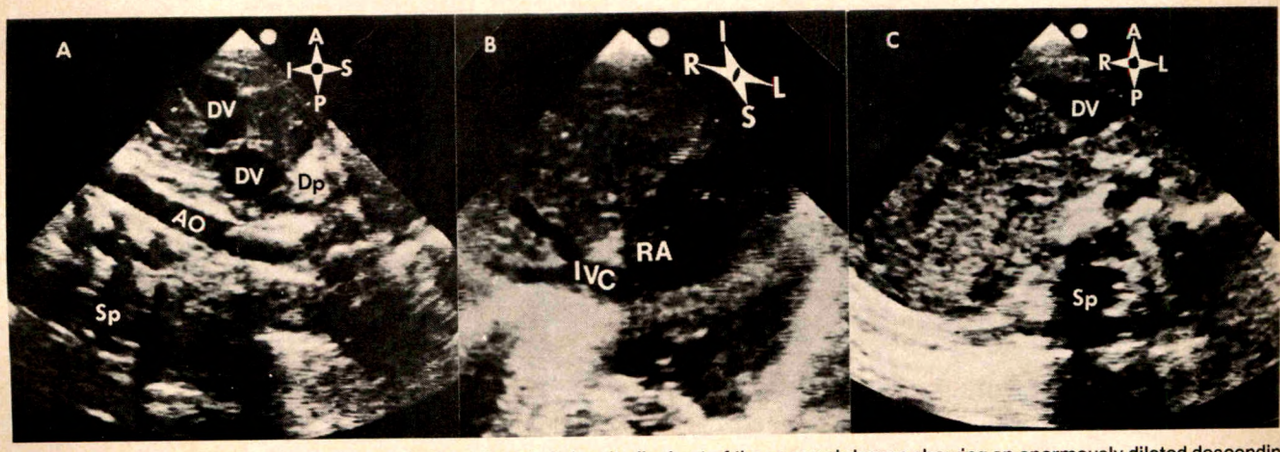

FIGURE 1. Two-dimensional echocardiogram from patient 1. **A,** longitudinal cut of the upper abdomen showing an enormously dilated descending vein (DV) in the liver. **B,** subcostal 4-chamber view showing the normal-sized inferior vena cava (IVC). **C,** short-axis cut of the upper abdomen showing communication of the descending vein with the portal veins. A = anterior; AO = descending aorta; Dp = diaphragm; I = inferior; L = left; P = posterior; PV = portal vein; R = right; RA = right atrium; S = superior; Sp = spine.

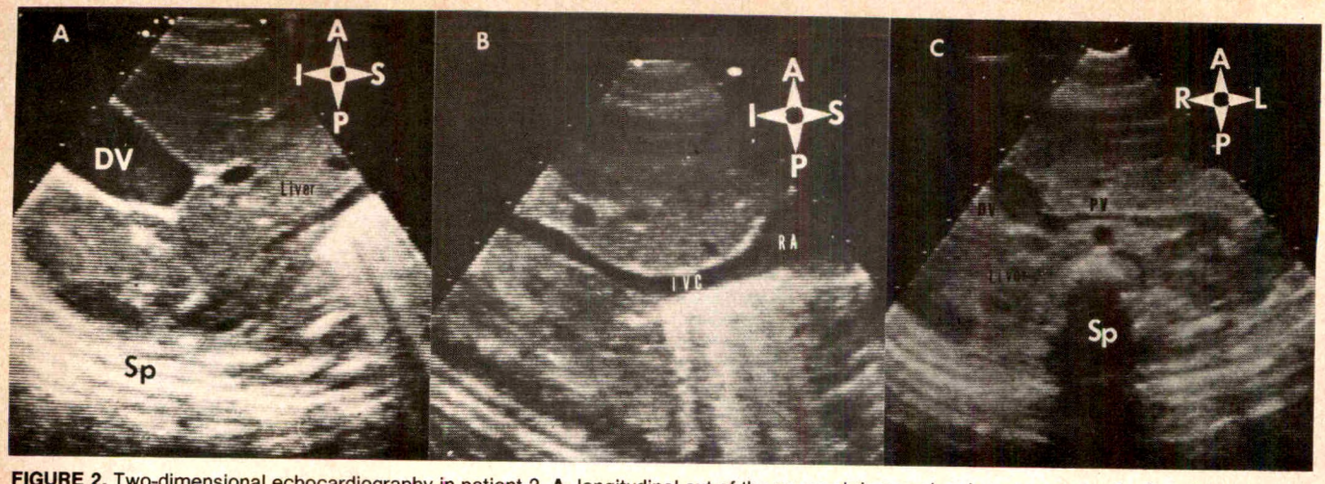

FIGURE 2. Two-dimensional echocardiography in patient 2. **A,** longitudinal cut of the upper abdomen showing an enormously dilated descending vein in the liver. **B,** normal-sized inferior vena cava draining into the right atrium. **C,** short-axis cut of the upper abdomen showing communication of the descending vein with the portal veins. Abbreviations as in Figure 1.

In 1 patient the diagnosis was further confirmed at operation.

Normal pulmonary venous connection to the left atrium can usually be identified by 2-D echo in 3 views: apical, subcostal and suprasternal.[1,3,5] However, failure in demonstrating pulmonary venous connection to the left atrium cannot by itself be construed as evidence for abnormal pulmonary venous drainage. Hence, demonstration of a dilated common pulmonary vein, usually behind the left atrium, is of paramount importance in the diagnosis of TAPVC. To achieve this, proper gain settings and careful scanning of the pulmonary veins in different echo planes by apical, subcostal and suprasternal approaches are mandatory, lest a diagnosis of normal pulmonary venous drainage be falsely made. This is exemplified in our experience with both patients. When examined initially from the subcostal position, we had a false impression of normal connection of the right upper pulmonary vein with the left atrium. Visualization of a dilated descending common pulmonary vein in the liver with subsequent scanning provided a clue for the diagnosis of TAPVC. The small, alleged pulmonary vein most likely represented 1 of the horizontal veins behind the left atrium just above the diaphragm. False connection of this pulmonary vein with the left atrium probably resulted from poor image resolution in this particular subcostal view. In a deeper subcostal cut of the long axis of the 2 atria, a mildly dilated pulmonary venous confluence, clearly separated from the left atrium, was demonstrated.

Acknowledgment: We thank Hsin Leen Tao and Grace T.C. Tsai for their secretarial assistance.

Two-dimensional echocardiography (2-D echo) is helpful in evaluating anomalies of the aortic arch in newborns, but has several limitations in adults.[1] We examined the role of computerized tomography (CT) together with 2-D echo and continuous-wave (CW) Doppler scanning in the noninvasive evaluation of aortic coarctation.

During the last 6 months we observed 5 patients, aged 8 to 54 years, with coarctation of the aorta confirmed by angiography. Three of them underwent surgery for elective repair by the subclavian flap technique. Two-dimensional echo was performed using a Diasonics 3400 R with a 2.5-MHz, phased-array transducer. A view of the aortic arch was obtained from the upper left sternal border and suprasternal notch. A continuous-wave Doppler echocardiogram was recorded with a Irex-Pedoff system, with a 2-MHz ultrasonic frequency; the transducer was placed in the suprasternal

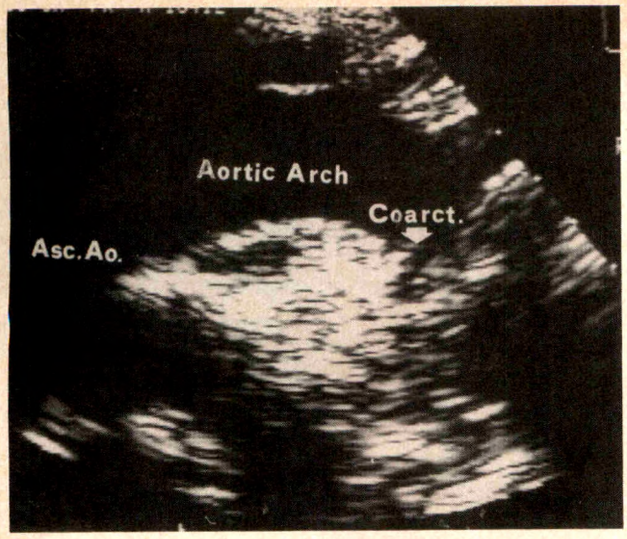

FIGURE 1. Two-dimensional echocardiographic image from the suprasternal notch of the ascending aorta (Asc. Ao.), aortic arch and descending aorta. The level of coarctation (Coarct, **arrow**) is shown.

notch in the first or second left intercostal space, with the probe directed toward the descending aorta. In the position in which the highest frequencies could be heard, peak velocity together with spectral analysis of the Doppler signal and electrocardiogram were recorded. As described previously,[2] maximal velocity across the obstruction can be used to calculate the pressure drop across the obstruction from the modified Bernoulli formula: $p^1 - p^2 = 4v^2$, where v is maximal velocity in the jet and p^1 and p^2 are the pre- and postobstruction pressures. The CT examination was done with a General Electric 9800 system using very short scan times (1.3 seconds, partial scan, 2 seconds) and high-contrast resolution (image reconstruction 512 × 512). Multiple CT scans were obtained during the infusion of 150 ml of contrast

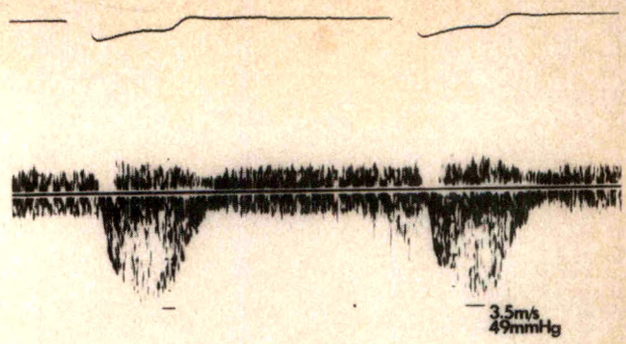

FIGURE 2. Continuous-wave Doppler recording of the maximal velocity flow obtained in the descending aorta after the obstruction. The gradient is derived from peak velocity.

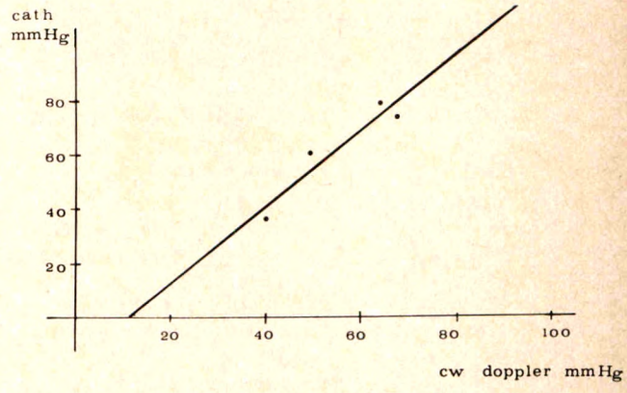

FIGURE 3. Relation between the systolic gradient obtained at catheterization and the pressure drop predicted by using simplified Bernoulli equation and continuous-wave (CW) Doppler (r = 0.94).

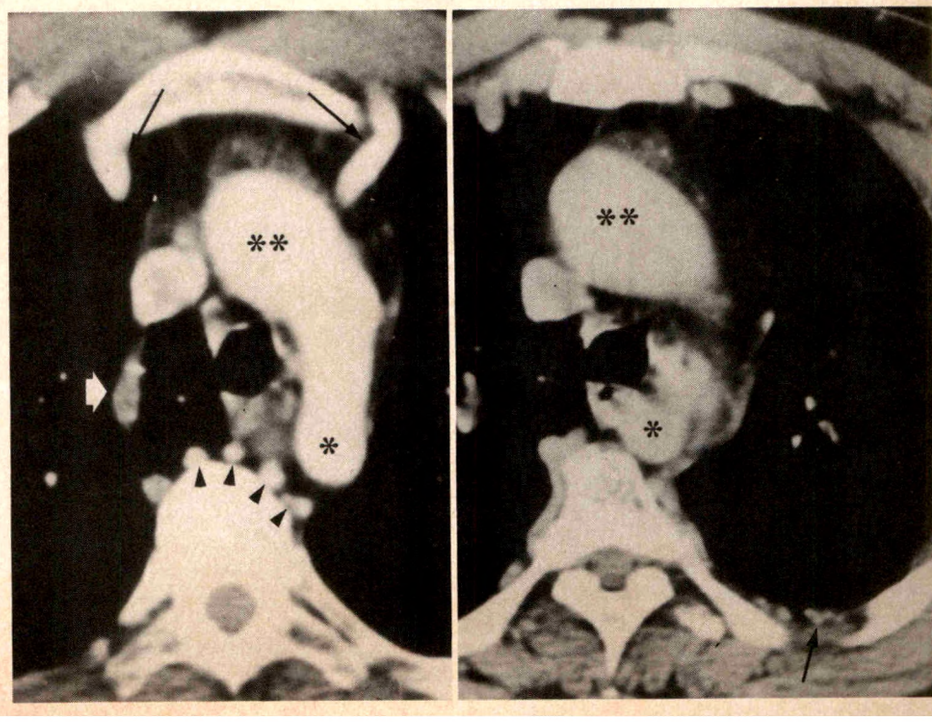

FIGURE 4. Left, computerized tomographic (CT) scan through the aortic arch. The difference in size between ascending (**) and descending (*) aorta is conspicuous. Ectasia of both internal mammary arteries (**black arrows**) are visible. Crown-like collateral circles can be seen in front of the vertebral body (**arrowheads**). The anomalous course of azygos vein (**white arrow**) is shown. **Right,** CT scan at the level of the aortopulmonary window. The difference in size between ascending (**) and descending (*) aorta is even more conspicuous. Intercostal collateral circles responsible for rib notches are quite visible (**arrow**).

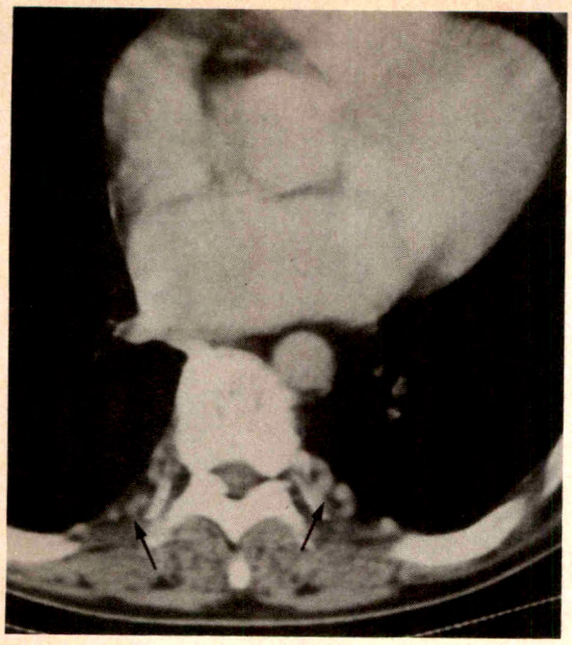

FIGURE 5. Computerized tomographic scan at the level of the left atrium. Paraspinal collateral circles are bilateraly visible (**arrows**).

medium from the thoracic inlet to the diaphragm. More scans were taken with less slice spacing and thickness in the aortic region. Sagittal, coronal and oblique reformatted CT images were also obtained. To better define the vascular structures of the chest wall, dynamic scanning at the tracheal bifurcation level was done with rapid injection of 40 ml of contrast medium. To confirm the previous data, pressure measurements and an aortogram were obtained in each patient under local anesthesia.

Two-dimensional echo evidence of coarctation was clear enough for diagnosis in only 2 patients (Fig. 1) because of technical problems in the suprasternal approach. By CW Doppler a high velocity jet from beyond the coarctation was recorded in 4 patients (Fig. 2) and the pressure drop was measured. Figure 3 shows the good correlation (r = 0.94) between peak pressure drop using CW Doppler and catheterization data.

CT scans (Fig. 4 and 5) provided 3 main types of information in all patients. These were: the shape and size of prestenotic and poststenotic aorta and great vessels; the amount of collateral circulation, which usually develops through the subclavian arteries (internal thoracic, transverse scapular) and intercostal arteries, the vertebral arteries and anterior spinal arteries; and the detection of other possible associated vascular anomalies.

It is well known[3] that angiography is the ideal instrument for the diagnosis and the surgical approach of aortic coarctation. Nevertheless, there are other noninvasive techniques that can be extremely useful in the definition of this malformation.[1] In the general population, chest x-rays can suggest the presence of aortic coarctation.[3] It is possible to recognize the "figure of 3" sign directly, or indirectly by the barium-filled esophagus. The frequency of visible rib notching correlates directly with age and inversely with the diameter of the coarctation measured in the resected specimen.[4] Glandy et al[4] reported that chest film reveals aortic coarctation in 66% of patients. In our experience CT was much more useful for the direct visualization and anatomic definition of all the different collateral roots. CT, sometimes together with 2-D echo, can anatomically determine the side and size of the obstruction. Although 2-D echo presents several technical problems in adults, it was nevertheless useful for the diagnosis of the bicuspid aortic valve, which is present in 85% of patients.[5] The big gap between traditional hemodynamic evaluation and noninvasive techniques has been overcome by CW Doppler, which provides pressure drop values. Recently Wyse et al[6] have reported that a high correlation (r = 0.85) was present between CW Doppler data and the arm-to-leg systolic blood pressure difference in 30 children affected by coarctation. In our experience CW Doppler presented a better correlation (r = 0.94) with the invasive data.

Arrhythmias and Left Ventricular Function in Chronic Alcoholics with Alcoholic Cirrhosis

ROBERTO S. GRIBALDO, MD
GIULIA S. POMINI, MD
FILOMENA SALE, MD
GIOVANNI MOLFESE, MD
LEOPOLDO COSTA, MD
PAOLO MAGLIO, MD
GIORGIO BOZZA, MD

Arrhythmias have been reported to occur in chronic alcoholics both as a secondary phenomenon to an overt cardiomyopathy[1] or as a primary event in absence of myocardial dysfunction.[2] Alcoholics with normal cardiac function may have severe arrhythmias after acute alcohol ingestion with return to normal rhythm during abstinence.[3] Because depression of myocardial function and arrhythmias occur both in animals and man[4] after acute alcohol consumption, the relation between ventricular dysfunction and arrhythmias in chronic alcoholism is difficult to establish. The role of alcohol in the onset of arrhythmias in chronic alcoholics with no episodes of acute ingestion and without overt alcoholic cardiomyopathy is also difficult to investigate because apparently healthy subjects may have arrhythmias.[5] We analyzed the arrhythmias and their relation to left ventricular (LV) function in a selected group of asymptomatic alcoholic patients with alcoholic cirrhosis and compared the findings with those from healthy nonalcoholic subjects.

Between April 1984 and September 1984, 12 chronic alcoholics, 7 men and 5 women, were studied at the Department of Medicine of Padua Medical Center. The patients' mean age was 37 years (range 30 to 45) and the criteria for admission in the study group were: consumption of 160 g/day of ethanol for at least 5 years; no evidence of congenital or acquired heart disease, lung disease, hypertension or diabetes; no therapy with cardiac medication or antiarrhythmic drugs; results of physical examination, electrocardiography and chest x-rays within normal limits; age younger than 45 years; and histologically ascertained hepatic damage (chronic alcoholic hepatitis in 6 patients and alcoholic cirrhosis in the remaining 6).

Twenty-four-hour Holter electrocardiograms, systolic time intervals and M-mode echocardiograms were recorded in each subject after 6 to 10 days (mean 7) of abstinence. On the day of Holter recording, serum potassium, calcium and (in 7 patients) magnesium levels were measured. Potassium and calcium levels were borderline, decreased or normal. The magnesium levels were slightly decreased in 2 alcoholic patients.

An age-matched control group of 10 nonalcoholic subjects (6 men and 4 women), selected among physicians and nurses of our department, underwent the same investigation except for the liver biopsy. Criteria of inclusion in the control group were absence of history of cardiovascular disease or symptoms and results of physical examination, electrocardiography and chest x-rays within normal limits.

Qualitative ventricular ectopy was described as uncomplicated (unifocal or uniform ventricular complex) and complicated (multiform or multifocal ventricular complexes, couplets, 3 or more consecutive ventricular premature beats and R-on-T phenomenon). Quantitative ventricular premature beats were classified as: not frequent (less than 30 beats/hour) and frequent (more than 30 beats/hour).

In the alcoholic group, 1,345 ventricular premature complexes and 41 supraventricular ectopies were found (Table I). Ventricular arrhythmias occurred in 5 of 12 patients (42%). The only patient of these 5 with frequent ventricular premature complexes also had complex arrhythmias, whereas the other 4 had occasional and simple ventricular premature complexes (Fig. 1). In the control group, 27 supraventricular and 1,234 ventricular complexes were detected (Table I). Only 3 patients (30%) in this group had arrhythmias: 2 had simple and occasional arrhythmias and only 1 patient had complex and frequent arrhythmias.

The mean value of echocardiographic indexes (shortening fraction, ejection fraction, LV diastolic thickness to radius ratio[6]) was normal and there was no significant difference in the 2 groups (Table II). The preejection period (PEP) corrected for heart rate according to the method of Weissler et al,[7] was significantly longer in alcoholics ($p < 0.05$) (Table III), but ejection time index was not different in the 2 groups. The PEP/LV ejection time ratio was slightly increased in alcoholics, but was not statistically significant ($p > 0.10$) (Table III).

The polygraphic and echocardiographic data were analyzed with the Student t test and F test. The comparison of the incidence of arrhythmias in the 2 groups was based on the χ^2 analysis with the Yates correction.

Our data suggest no difference in the rhythm disturbances occurring between chronic alcoholics without acute influence of alcohol and those found in normal persons. The distribution of arrhythmias was not sta-

tistically different ($p > 0.90$) in the 2 groups. Ventricular arrhythmias occurred in 5 alcoholics and in 3 healthy subjects, but frequent and complicated arrhythmias occurred in only 1 subject in each group. Our data are in agreement with those recently reported by Greenspon et al[3] and Zoneraich et al,[8] who showed that chronic alcoholics not under the influence of acute alcohol ingestion do not have significant arrhythmias.

Myocardial contractility (ejection and shortening fraction) were normal. In our series, the lack of any increase in wall thickness, considered by some investigators[6,9] as a sign of initial alcoholic cardiomyopathy, may be explained by the relatively younger age of our patients compared with others,[6,9] or possibly to a different kind of alcohol ingested. The population of English-speaking countries is more inclined to drink liqueurs rather than wine; wine is the most common alcoholic drink in the Mediterranean areas.

The discrepancy between the abnormality of systolic time intervals and the normal values of echocardiographic indexes has also been noted by Askanas et al.[10] They postulated decreased compliance of the hypertrophied left ventricle as the probable cause for the abnormal systolic time intervals. Our data do not appear to support his hypothesis, because in our patients the thickness of the left ventricle was not increased. In 2 alcoholic patients, the PEP index was clearly prolonged (154 ms), but neither patient had significant arrhyth-

mias. However, the only patient with complex and frequent arrhythmias also had a significant prolonged PEP index (147 ms).

Despite the small number of patients examined, our impression, based on the results obtained, is that the arrhythmogenic role of alcohol if not acutely ingested) is relatively unimportant. Our study confirms the finding that chronic alcoholics have an incidence of arrhythmias similar to normal subjects.

Left Ventricular Thrombi in Association with Normal Left Ventricular Wall Motion in Patients with Malignancy

THOMAS S. DeGROAT, MD
R. PARAMESWARAN, MD
PAUL M. POPPER, MD
MORRIS N. KOTLER, MD

The ability of 2-dimensional echocardiography to demonstrate intraventricular thrombi has stimulated interest in the natural history of thrombi and their potential to embolize.[1] Since most intraventricular thrombi occur in conjunction with regional wall motion abnormalities, their occasional association with normal ventricular motion and the possible role in systemic embolization in such patients has not been emphasized. We report left ventricular (LV) thrombi in 2 patients with normal LV wall motion who had embolic events.

Case 1: *A 43-year-old man with myelogenous leukemia, without a history of cardiac disease, was admitted with sudden onset of pain and numbness in both legs. Both legs were cold, pale and pulseless. Findings of cardiac examination were normal. The electrocardiogram was normal except for nonspecific T-wave abnormalities. The white cell count was 29,800 mm^3 with 21% eosinophils. Angiography confirmed embolic occlusion of both popliteal arteries. A Fogarty embolectomy was performed and large clots consisting of organizing thrombus with fibrin and red cells were recovered. An echocardiogram revealed normal cardiac valves and cardiac chambers. A large, mobile thrombus was noted within the left ventricle. LV wall motion was normal and the endocardium appeared normal (Fig. 1, A and B). Intravenous heparin administration was started. Several weeks later, embolic occlusion of the right femoral artery occurred, again requiring embolectomy. Repeat echocardiography revealed the thrombus to have decreased in size. Wall motion remained normal. The patient's recovery was uneventful and he was discharged on warfarin therapy.*

Case 2: *A 57-year-old woman with metastatic oat cell carcinoma of the right lung was admitted with a pathologic fracture of the right femur. There was no history of cardiovascular disease. Cardiovascular examination was normal. The hemoglobin was 8.7 g/dl. The white blood cell count was normal. The electrocardiogram showed nonspecific ST-T abnormalities. After surgery for the pathologic fracture, tachycardia developed. An echocardiogram revealed normal LV wall motion and a mobile apical thrombus (Fig. 1, C and D). Intravenous heparin was begun, but several hours later she had sudden right hemiplegia. A computed tomographic scan was normal. A repeat echocardiogram showed a signif-*

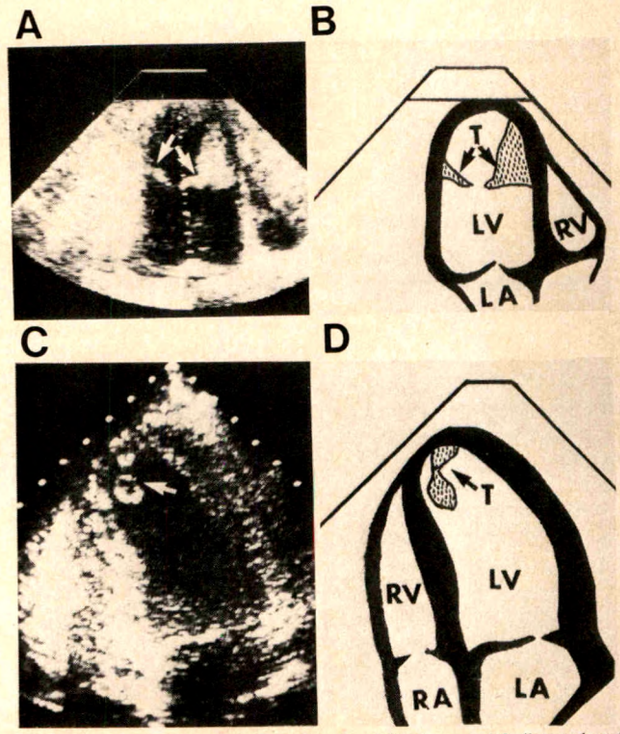

FIGURE 1. A and **B,** representative diastolic frame of 2-dimensional echocardiography in case 1. Note the large thrombus (T) (**arrows**) within the left ventricle (LV). **B** and **C,** a pedunculated apical thrombus in case 2. LA = left atrium; RA = right atrium; RV = right ventricle.

From the Cardiology Section, Albert Einstein Medical Center, York and Tabor Roads, Philadelphia, Pennsylvania 19141. Manuscript received March 22, 1985; revised manuscript received April 26, 1985, accepted April 29, 1985.

icant decrease in the size of the thrombus. A diagnosis of cerebral embolism was made and anticoagulant therapy was continued. The patient's condition progressively deteriorated and she died 2 weeks later.

In the 2 patients described, the findings were typical of thrombi; however, in contrast to previous studies,[2,3] the LV wall motion was normal. The occurrence of systemic emboli was confirmed in case 1 and appeared highly likely in case 2. Both patients had a marked decrease in the size of the LV thrombus after the embolic events on follow-up echocardiographic studies. Although the relative role of thrombus mobility could not be adequately defined, it appears reasonable to assume that normal ventricular systolic function was a contributing factor in causing emboli.

The mechanism of development of thrombi in the presence of normal ventricular wall motion is unclear, but it is notable that both patients had an underlying malignant disease that was associated with an increased incidence of thrombosis.[4] In addition, in case 1 there was marked eosinophilia, which in the setting of idiopathic hypereosinophic syndrome has been associated with intracardiac thrombi and embolism.[5]

Prior studies have suggested that 2-dimensional echocardiographic studies are of limited value in the assessment of patients with systemic embolic without clinical evidence of underlying heart disease.[6] Our observations in these 2 patients suggest that 2-dimensional echocardiography may be of value even if underlying heart disease is not suspected. This may be particularly true in patients with an underlying malignancy. The combination of LV thrombi and normal wall motion may increase the likelihood of subsequent embolic events.

Benign Intracardiac Thyroid Mass Causing Right Ventricular Outflow Tract Obstruction

RICHARD J. SHEMIN, MD
JAMES D. MARSH, MD
FREDERICK J. SCHOEN, MD, PhD

The presence of thyroid tissue within the heart is rare. Most reports have described intracardiac metastases from thyroid carcinoma. Herein we describe for the first time a benign intracardiac thyroid mass that was successfully excised.

A 58-year-old woman with past systemic hypertension was noted to have a systolic ejection murmur at age 52 years. By age 58 years the intensity of the murmur had increased to grade 4/6 and was present along the left sternal border. It radiated to the upper sternal area, and an associated palpable thrill was present. The second heart sound was single. The patient had noted recently a slight decrease in exercise tolerance. Chest radiograph revealed a normal-sized heart, clear lungs and a prominent main pulmonary artery. The electrocardiogram revealed borderline right ventricular hypertrophy. On admission to the hospital, a 2-dimensional echocardiogram demonstrated a 2.5 × 1.5 cm, ovoid right ventricular (RV) outflow tract mass attached to the RV side of the ventricular septum, proximal to the pulmonary valve with possible involvement of the cusps. During the cardiac cycle, the mass moved with a ball valve-like motion. The heart was normal in size, configuration and chamber size (Fig. 1). The patient underwent surgical exploration with use of cardiopulmonary bypass. The pulmonary artery was opened, revealing the ovoid mass herniating through the pulmonary valve (Fig. 1). The valve cusps were normal. By retracting the valve cusps, the mass was visualized, originating just below the pulmonary valve and extending down along the ventricular septum with a broad base. The mass

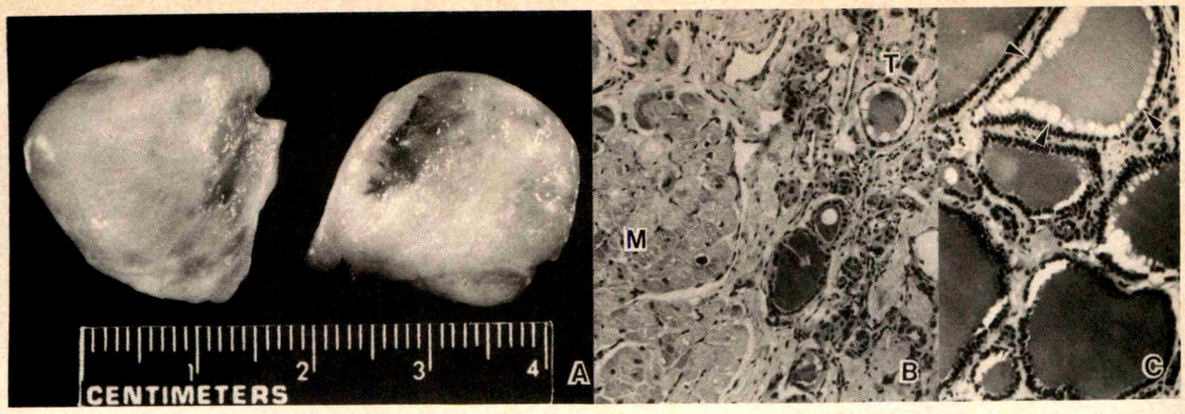

FIGURE 2. A, gross and histologic appearance of surgically resected cardiac thyroid mass. **Left,** external surface; **right,** cut surface. The appearance of the sectioned surface strongly resembles that of the normal thyroid gland. **B,** photomicrograph showing myocardium (M) at **left,** adjacent to large colloid-containing follicles resembling thyroid (T). **C,** photomicrograph showing large follicles and the peripherally scalloped colloid (**arrowheads**) characteristic of hyperplastic thyroid. Hematoxylin-eosin stain; × 325, reduced 35%.

was excised with a margin of normal muscle on the ventricular septum (Fig. 1). The patient recovered uneventfully. The excised mass was "rubbery" and measured 2 × 2 × 1 cm (Fig. 2). The external surface of this mass had a dense fibrous capsule. Microscopically, the mass was composed of thyroid tissue that had variations in follicular size, focal hemorrhage, fibrosis, and calcific and cholesterol deposits consistent with adenomatous hyperplasia. It was not neoplastic and it was consistent with an intracardiac ectopic rest.

Thyroid function tests revealed a T_4 of 8.6 mg% (normal, 5 to 11 mg%), a thyroid binding globulin index of 0.95 (normal, 0.85 to 1.10) and a thyroid stimulating hormone of 2.5 μU/ml (normal, less than 5 μU/ml). A ^{123}I scan revealed a normal thyroid gland in the neck and no evidence of other ectopic foci.

This is the first recorded case of a benign thyroid rest of the RV outflow tract found during life. A previous case was found at autopsy in a 51-year-old woman with a systolic murmur.[1] The patient died of cerebral angioblastoma; at autopsy she was found to have a 4 × 5 × 6 cm mass originating from the RV aspect of the ventricular septum, just below the pulmonary valve and the mass obstructed the RV outflow tract. It too was composed of benign thyroid tissue. She had a normal thyroid gland.

With the exception of our patient and the one reported by Rogers and Kesten,[1] all studies of intracardiac thyroid tissue have reported metastases. A solitary thyroid metastasis to the heart has not been reported. Both cases of benign ectopic thyroid rests originated from the right side of the ventricular septum. During the patients' middle age, they grew to a significant degree to cause RV outflow tract obstruction and a clinical systolic ejection murmur. Both patients had a normal thyroid gland in the neck. The patient described in this report had normal thyroid function. The RV outflow tract is often a site for symptomatic cardiac metastatic tumors and thyroid carcinoma frequently metastasizes to the heart. Although the potential for malignant transformation of intracardiac ectopic thyroid would seem to exist, primary thyroid cancer of the heart has not been reported.[2] Thus, the presence of thyroid tissue in the heart does not portend a poor prognosis; complete resection is indicated and the condition is curable.

Manuscript received March 6, 1985; revised manuscript received April 18, 1985, accepted April 23, 1985.

Transvenous pacemaker electrodes and any other central venous catheter may cause superior vena cava (SVC) thrombosis. When more than 1 pacemaker electrode is present, contact between the electrodes accentuates the thrombotic tendency and may cause local injury and stenosis of the vessel. We present a patient in whom 2 pacemaker electrodes caused stenosis and thrombosis of the SVC, and the obstruction was subsequently successfully treated with streptokinase and transluminal angioplasty.

A 71-year-old woman had a permanent transvenous pacemaker implanted through the right cephalic vein in 1968 because of complete atrioventricular block. In April 1981, a second wire was inserted, using the left cephalic vein because

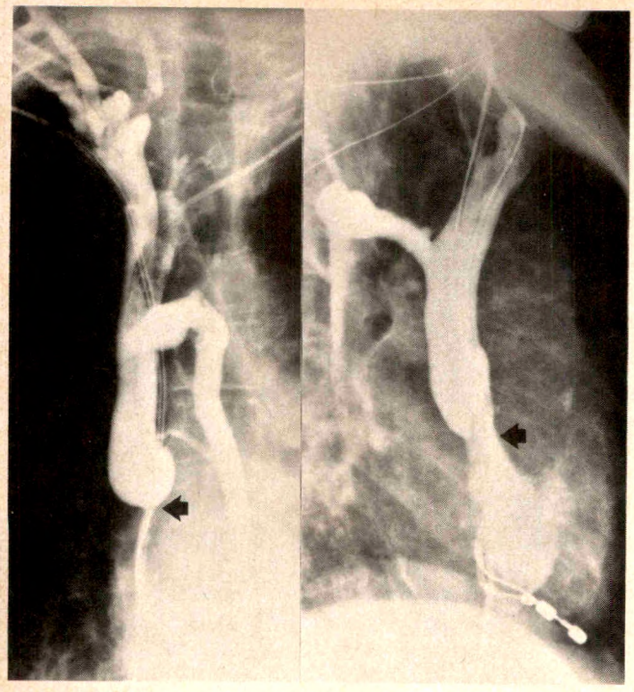

FIGURE 1. Left, upper extremity venogram with subtotal occlusion of the superior vena cava near the right atrium (**arrow**). The azygous vein is distended. **Right,** postangioplasty venogram showing wide patency of the superior vena cava at the previous site of stenosis (**arrow,** lateral projection).

of malfunction of the original lead, which was left in place. The patient did well for 4 months until August 1981, when she awoke with nasal stuffiness and dyspnea, and noted swelling of her eyelids and lips. Cyanosis of the lips, blurred vision and headache were also present. The blood pressure was 145/105 mm Hg, pulse 76 beats/min and respirations 32 breaths/min. Cyanosis and nonpitting edema of the head and thorax were seen. There was pronounced jugular venous distention. Chest roentgenogram on admission showed 2 pacing electrodes, their tips in the right ventricular apex and 1 of the electrodes attached to its battery pack in the left infraclavicular area. The other electrode had been amputated; its free end was below the right clavicle. Bilateral upper-extremity venograms showed extensive thrombosis of the left brachiocephalic and right subclavian veins. The clot extended into the SVC. The patient was treated with streptokinase for 48 hours, heparin therapy for 1 week, and discharged on warfarin sodium after a venogram showed patency of the subclavian and innominate veins and SVC.

The patient did well for 30 months, until April 1984, when she again presented with symptoms of SVC obstruction. A venogram showed occlusion of the SVC. Fibrinolytic therapy was again administered. No relief of the signs or symptoms had occurred at 48 hours and a repeat venogram showed thrombosis and stenosis at the SVC (Fig. 1, left). Percutaneous transluminal angioplasty was performed, initially using a balloon 4 cm long and 12 mm in diameter. After successful dilation, a 20-mm balloon was placed at the stenosis and the area was again dilated. A repeat venogram after the angioplasty showed that the SVC was widely patent (Fig. 1, right). No pulmonary emboli were encountered after the procedure. The patient was discharged in an asymptomatic state after a 12-day hospitalization. She has had no further symptoms in 10 months.

The first report of a complication of pervenous pacing was reported by Prozan et al in 1968.[1] They described a patient who died of multiple pulmonary emboli. On autopsy, the source was identified as clot on the pacing wire. Occasionally, the innominate or subclavian vein will be obstructed after pacemaker insertion. Studies have reported an incidence of partial obstruction of these vessels of between 31 and 50%.[2,3] Up to one-third have total occlusion.[2] Clot may extend into the SVC, but total occlusion here is rare and development of the SVC syndrome is even rarer. Frequently, a malfunctioning pacing wire cannot be removed from the right ventricle because of fibrous entrapment. If a second wire is inserted, stenosis of the vessel may occur at the site of their intersection. Removal of the wire and anticoagulation therapy has been used to prevent further thrombosis and to allow time for development of collateral flow in patients with partial or complete occlusion. This may be effective, even in patients with SVC syndrome. Thrombolytic therapy has been used successfully, although recurrent thrombosis at a later date is frequently seen, and is particularly common in cases where stenosis of the SVC is present in addition to thrombosis.[4] Insertion of a bypass graft is an alternative therapy.

Transluminal angioplasty has been used in the inferior vena cava to dilate stenoses in 5 patients with the Budd-Chiari syndrome.[5] Angioplasty is also helpful in dilating congenital or postoperative venous channels.[6] If the obstruction of the vena cava is purely stenotic or even associated with thrombus, angioplasty may be helpful. If a single balloon is not large enough, 2 or more balloons can be easily used.

Diagnosis of Cardiac Tumors in Infants by Magnetic Resonance Imaging

ROBERT A. BOXER, MD
MICHAEL A. LaCORTE, MD
SHARANJEET SINGH, MD
JAMES SHAPIRO, MD
MILES SCHILLER, MD
MITCHELL GOLDMAN, MD
HARRY L. STEIN, MD

Primary cardiac tumors in infancy are rare, with an estimated necropsy incidence of 0.027%.[1] Traditionally, cardiac catheterization has been used to establish and confirm the diagnosis of intracardiac tumors.[2] Recently, 2-dimensional (2-D) echocardiography has proved to be a reliable, noninvasive tool for diagnosis.[3] We report the use of magnetic resonance imaging (MRI) for evaluation of 4 infants with intracardiac tumors. In each patient, detailed visualization of the intracardiac mass was achieved using an electrocardiogram-gated MRI technique.

MRI was performed with a commercially available superconducting magnetic (Technicare, Inc.) operating at 0.6-tesla field of strength. A multislice technique affording up to 16 adjacent 0.75- to 1-cm sections, depending upon the repetition time (TR), was used and the images were reconstructed with a 2-D Fourier transformation technique. The reconstruction matrix was 128 vertical by 256 horizontal pixels with 256 gray levels. All patients were imaged in coronal, transverse, sagittal and left anterior oblique planes using the multislice technique. Spin-echo pulse sequences were obtained with echo delay times of 30 ms. The TR (in ms) was set according to each patient's heart rate, by the formula (60,000/HR) − 50, with most TR varying between 500 and 1000 ms.

All images were gated using a Hewlett Packard telemeter. The transmitter was placed adjacent to the patient just outside the coil and the receiver was located in the control room. All sequences were initiated on the R wave of the electrocardiogram. All patients were sedated with intramuscular meperidine (2 mg/kg), promethazine (0.5 mg/kg) and chlorpromazine (0.5 mg/kg), given 1 hour before the procedure.

At the time of presentation, all patients had undergone 2-D echocardiography, which established the diagnosis of an intracardiac tumor. Patient age at MRI study ranged from 3 to 12 months. The site of the tumor was the right ventricle in 2 infants, right atrium in 1 infant and left ventricle in 1. Two infants had tuberous sclerosis. One patient (no. 1) had surgery, at which time a rhabdomyoma was removed from the right ventricle. Three patients are currently asymptomatic and 1 patient (no. 4), with a left ventricular tumor, died suddenly at age 13 months.

The electrocardiogram-gated MRI technique afforded excellent visualization of the extent and site of attachment of the tumor in all 4 patients. In patient 1, with a right ventricular tumor, MRI revealed a well circumscribed elliptical mass attached to the right ventricular anterior wall (Fig. 1). In patient 2, the right ventricular tumor was confined to the apex of the ventricle and was attached to the ventricular septum (Fig. 2).

In patient 3, with a right atrial tumor, the mass was well seen on transverse and coronal views. The MRI study showed a large, solitary, spherical mass attached to the lateral wall of the high right atrium near the entry of the superior vena cava (Fig. 3).

In patient 4, with a left ventricular tumor, the MRI study revealed a large left ventricular mass bulging into and significantly compromising the volume of the ventricular

chamber (Fig. 4). The tumor was noted on all imaging planes, but was best visualized on the transverse and coronal views.

Previous studies have shown that electrocardiogram-gated MRI is a safe, noninvasive technique that produces accurate, detailed visualization of intracardiac anatomy in many congenital cardiac defects.[4,5] MRI is ideally suited for cardiovascular studies because of the naturally occurring high degree of contrast between moving blood and the more stationary cardiac tissues. An additional advantage, especially in infants and children, is the lack of need for intravenous contrast agents or exposure to ionizing radiation.

A recent study in adults and children has established the validity of MRI in the evaluation of cardiac and paracardiac masses.[6] In that report, an 18-month-old child with a congenital cardiac tumor was presented. In the current study, with the use of electrocardiographic gating, high-resolution images of intracardiac tumors and their relation to normal cardiac structures were obtained in 4 infants. Because a wider field of view can be obtained and the quality of images is not adversely affected by adjacent lung tissue and bone, the MRI technique afforded excellent delineation of the intracardiac masses.

Cardiac Hydatid Cyst Simulating Tricuspid Stenosis

ÇETIN EROL, MD
ISFENDIYAR CANDAN, MD
HAKKI AKALIN, MD
AHMET SONEL, MD
CELAL KERVANCIOĞLU, MD

Cardiac echinococcosis is rare, occurring in only 0.5 to 2% of patients with echinococcal disease.[1] Echocardiography has been used to diagnose and detect intracardiac echinococcosis.[2–5] We present a patient with ventricular septal hydatid cyst, diagnosed by 2-dimensional echocardiography, simulating tricuspid stenosis.

A.P., a 23-year-old woman, was admitted complaining of dyspnea on exertion, cough and hemoptysis for 3 months. She was in no distress. The blood pressure was 110/70 mm Hg. The neck veins were distended and the a *wave was prominent. The lungs were clear. A musical diastolic murmur was heard at the left, second and third intercostal area. The electrocardiogram showed sinus tachycardia, right atrial enlargement and incomplete right bundle branch block. Telecardiography showed a prominent right atrial border, mild cardiomegaly and decreased pulmonary vasculature. Tricuspid stenosis was diagnosed by M-mode echocardiography (Fig. 1). Two-dimensional echocardiography disclosed a large cystic tumor with multiple septa on the upper part of the ventricular septum, protruding into the right ventricular cavity and obstructing the tricuspid valve (Fig. 2). Phonocardiography and jugulography showed a prominent* a *wave, early decrescendo and mid-diastolic murmurs (Fig. 1). Right ventricular cineangiography, at which radiopaque material was given in the right atrium, showed 3 lobulated masses protruding into the right ventricle (Fig. 3). The right atrial pressures were elevated. Right ventriculotomy under total cardiopulmonary bypass was performed. A 5 × 3 cm cyst was found under the septal leaflet of the tricuspid valve, localized in the upper third of the ventricular septum. The valve was intact. Numerous germinative membranes and daughter cysts were seen in the cystic cavity. There was no ventricular septal defect at the region where the cyst was based. All of the daughter cysts were removed. After resection of the excess of the pocket, it was closed with Teflon® pledget sutures. The heart began to pump spontaneously. On the second postoperative day, pulmonary edema developed and she died 60 hours after the operation.*

From the Departments of Cardiology and Cardiovascular Surgery, Faculty of Medicine, University of Ankara, Sihhiye-Ankara, Turkey. Manuscript received March 18, 1985; revised manuscript received May 3, 1985, accepted May 6, 1985.

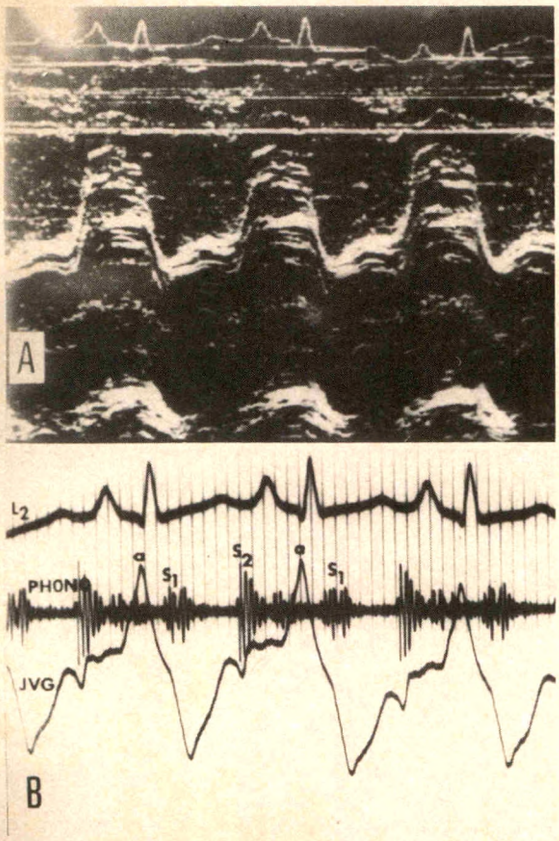

FIGURE 1. A, tricuspid valve showing tricuspid stenosis on M-mode echocardiography. **B,** simultaneous recording of electrocardiogram, phono- and jugulogram. Note the 2 different diastolic murmurs on phono and prominent *a* waves on jugulogram (JVG).

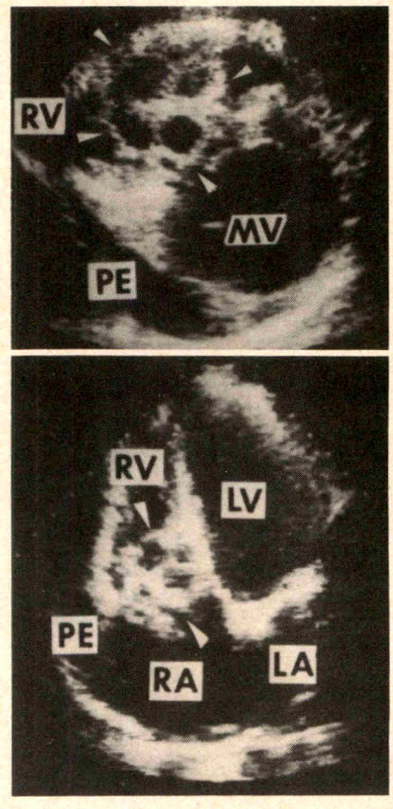

FIGURE 2. Top, 2-dimensional echocardiogram in the short-axis view showing the multiseptated cystic structure (**arrows**) located on the interventricular septum. **Bottom,** apical 4-chamber view showing the same structure (**arrows**) just under the tricuspid valve. LA = left atrium; LV = left ventricle; MV = mitral valve; PE = pericardial effusion; RA = right atrium; RV = right ventricle.

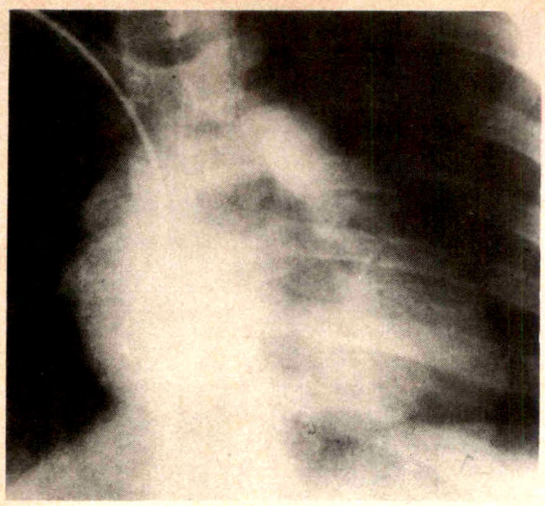

FIGURE 3. Angiographic study of the patient. Posteroanterior view shows 3 lobulated structures in the right ventricle.

Necropsy revealed no ventricular septal defect or cardiac tamponade. The tricuspid valve was intact. The left lung was solid and several cysts were removed from the left main pulmonary artery and its branches. The right lung was seen partially expanded; one of 2 blebs on it had ruptured.

Although there are many reports about hydatid cysts obstructing right ventricular outflow tract, cases with tricuspid valve obstruction are rare.[1,6] In our patient, the cyst was located in the upper third of the ventricular septum of the right side of the heart and simulated tricuspid stenosis. Multiple emboli caused subacute and acute pulmonary hypertension and finally fatal pulmonary insufficiency.

Acknowledgment: We gratefully acknowledge the curiosity of our echo technician, Ayten Solak, who called our attention to the case.

Echocardiographic Detection of Circulating Blood in Normal Canine Hearts

MIGUEL A. GARCIA-FERNANDEZ, MD
JOSE LOPEZ-SENDON, MD
ISABEL COMA-CANELLA, MD
JOSE SOTILLO, MD

Experimental studies by Sigel et al[1] show that blood is echogenic in vitro. The echogenicity of blood also has been demonstrated in vivo but has always been related to reduced blood flow during, for example, left ventricular aneurysm[2] and left atrial dilatation secondary to long-standing mitral valve disease.[3] In the same way, it is possible to observe homogeneous echoes of low acoustic density that are due to blood stasis in the pericardial cavity when it contains liquid blood.[4] This report describes a study in dogs in which the movement of circulating blood was detected by echocardiography.

Nineteen adult mongrel dogs weighing 16 to 32 kg were anesthetized with intravenous sodium pentobarbital, 25 mg/kg, and intubated. Room air ventilation was maintained by means of a Harvard respirator. The chest was opened by a midsternal incision and the pericardium was maintained intact. Fluid-filled 5Fr polyvinyl catheters were inserted through the superior vena cava and carotid artery. Right atrial, right ventricular, pulmonary artery, aortic and left ventricular pressures were recorded using a Gould transducer and a Siemens Minograph 82. Cardiac output was measured by thermodilution; a Swan-Ganz catheter was placed in the pulmonary artery through a jugular vein and an Edwards 9500 A cardiac output computer was used. Three successive determinations were made, and the average was calculated.

Several short- and long-axis views were obtained by placing the transducer directly on the heart, taking special care not to press on the cavity. A Mark 600 ATL echocardiograph with a 7-MHz transducer was used. In 4 dogs, images were also obtained with a 3-MHz transducer. In all dogs a simultaneous M-mode recording was made in the zone where the echoes produced by the blood were more intense. Special care was taken to set the echocardiograph controls in a high-gain setting to facilitate recording of the echoes produced by the blood. With a low-gain setting these images were less visible. All studies were recorded on a Panasonic VHS vidoetape recorder for subsequent analysis. Echocardiographic images were recorded before and after the introduction of catheters into the heart cavities and no differences were observed between them.

In the right ventricular cavities of 16 dogs, intracavitary echoes showing dynamic variations in shape and conformation from beat to beat were obtained. Intracavitary echoes were characterized by low amplitude and variable density, showing a circular, whirlpool-like movement. The maximal echo intensity was observed between the leaflets of the tricuspid valve in diastole. The correspondent M-mode image was recorded as a set of linear echoes, similar to those found

From the Servicio de Cirugia Experimental, Ciudad Sanitaria La Paz, Madrid, Spain. Dr. Garcia-Fernandez's current address: Escuela Nacional de Enfermedades del Torax, Ciudad Universitaria, Madrid. This study was supported in part by grants from the Comisión Asesora de Investigación Cientifica y Técnica (0647/81) and from Kontron S.A. Madrid, Spain. Manuscript received April 16, 1985, accepted April 22, 1985.

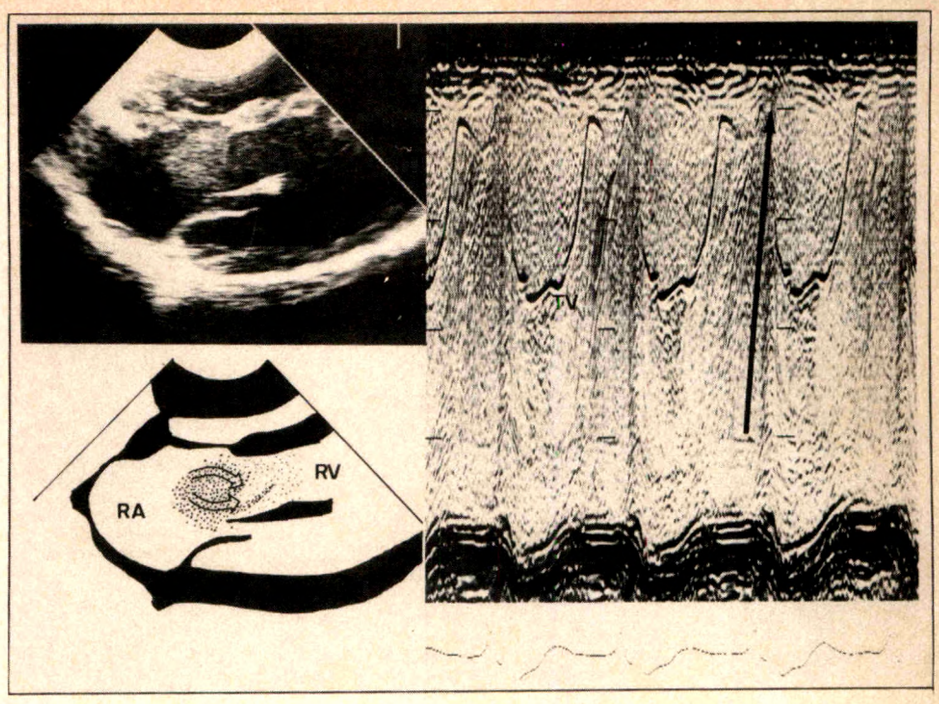

FIGURE 1. Top left, 2-dimensional echocardiogram, parasternal long-axis view of the right ventricle (RV). **Bottom left,** dynamic echoes (**curved arrows**) produced by blood can be seen between the anterior and posterior tricuspid leaflets. **Right,** M-mode echocardiogram at the level of the tricuspid valve (TV), showing the echoes produced by blood passing through the tricuspid valve in diastole. Note the increase of the echoes when atrial contraction occurs (**long arrow**). RA = right atrium; RV = right ventricle.

in right cavities by contrast echocardiography, particularly at the time of tricuspid valve opening. In all dogs an evident increase in the intensity of the echoes during atrial systole, coincident with the tricuspid "a" wave in the M-mode echocardiography, was produced (Fig. 1).

Images of the left ventricular cavity, similar to those of the right side, were observed in 6 dogs, 3 of them also showing echoes in the right-sided cavities. Whirlpool-like echoes, showing clear phasic variations in shape from beat to beat, which were indicative of a fluid state, were recorded by 2-dimensional echocardiography (Fig. 2); the maximal intensity was in the left ventricular cavity. Using M-mode echocardiography, stratified linear echoes were observed in the same 6 dogs. In the other 3 dogs, no intracavitary echoes were observed throughout the study.

In all dogs, cardiac output was within the normal range (mean 110 ± 16 ml/kg). There was no significant difference compared with a group of normal dogs previously studied in our laboratory (cardiac output 100 ± 30 ml/kg) (unpublished observation). Right- and left-sided pressures were always within the normal range.

For the first time, our results show that blood can be echogenic in the absence of blood stasis under experimental conditions. The causes of this finding are related to the special characteristics of the study, because the technical aspects of the echocardiographic examination and the ultrasonic frequency are important factors in any study on the acoustic properties of blood. We used a 7 MHz transducer placed directly on the heart. Longitudinal and lateral or angular resolution increases when using high-frequency echo transducers, despite the decrease in depth of penetration.[5] This increase in resolution probably permits images of blood in the fluid state to be obtained. In 4 dogs we used a 3-MHz transducer and could not visualize the blood echoes that were

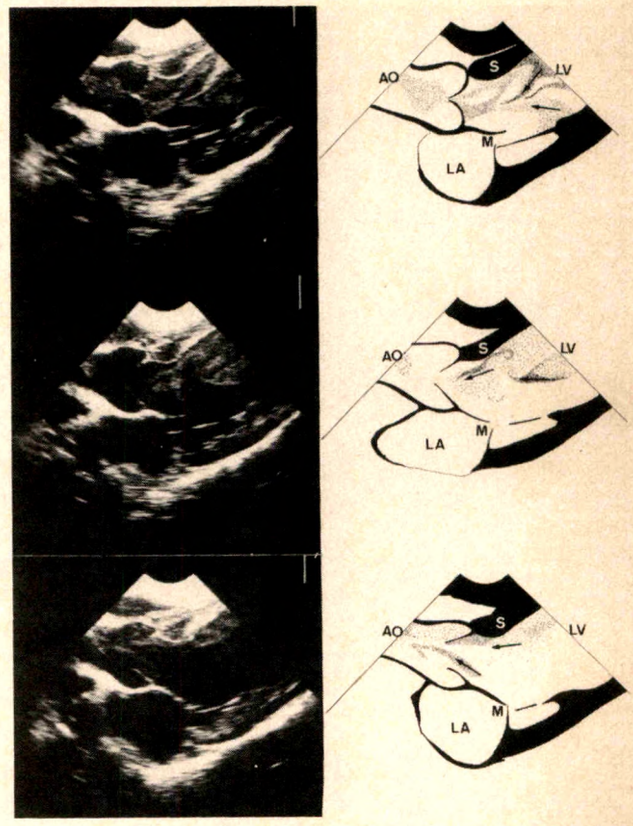

FIGURE 2. Two-dimensional echocardiogram, parasternal long-axis view of the left ventricle (LV) showing whirlpool-like echoes that show evident phasic variations in formation from 1 cardiac cycle to another, indicative of a fluid state. AO = ascending aorta; LA = left atrium; M = mitral valve; S = ventricular septum.

easily seen with the 7-MHz transducer. This finding is in accordance with the studies of Mikell et al,[2] who showed that the echocardiographic patterns of blood stasis in dogs with important segmental contraction abnormalities were more easily seen with a 5-MHz than with a 3-MHz transducer. Likewise, in patients with apical wall motion abnormalities, the echocardiographic pattern of blood stasis observed when using a 5-MHz transducer is only scarcely visible when using a 3-MHz transducer.[2]

As our data indicate, the echocardiographic images of circulating blood are detected more frequently in the right ventricular cavity. Several factors can be adduced to explain these findings. The left ventricle is situated more deeply than the right ventricle and, because of the reduction in depth penetration of high-frequency transducers, it would be more difficult to obtain well-defined images from very deep areas of the heart. Nevertheless, there must be some factors other than the depth that can facilitate the appearance of blood echogenicity in the right ventricle. In 4 dogs the short-axis view showed echocardiographic images of blood flow in the right atrium and the right ventricle but not in the aorta, even though the aorta is closer to the transducer than the right atrium in this view. The better visualization of venous blood compared with arterial blood can probably be explained by their different physicochemical and rheologic characteristics. Density and viscosity of blood increase with a higher content of CO_2.[6] Therefore, viscosity and density are greater in venous blood than in arterial blood, a factor that may facilitate echogenicity.

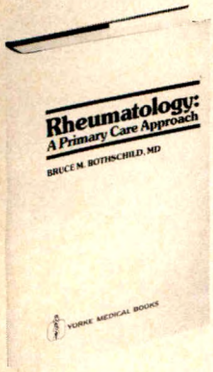
The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind



Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V.A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8, $42.50, 430 pp., illus., 1982.

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Abbreviated Table of Contents

Section 1 **Investigative Techniques**
Section 2 **Patterns**
Section 3 **Management**

"This compact, well-designed and generally informative volume is a useful reference for the management of rheumatic disease by physicians who deliver primary care. The family physician will undoubtedly use this frequently as a reference."
Charles M. Plotz, MD American Family Physician

"This book is a good primer for students, residents, and health professionals who would like a glimpse into rheumatology. It can be recommended for all but the specialist (but perhaps the specialist should read it, too, to see what those he is training are learning)."
George E. Ehrlich, MD JAMA September '83

This is a superb text by a sensitive, concerned, organized author of international repute . . . Each chapter is well outlined, concise, practical, and has a current and appropriate bibliography at the end . . . a skillfully structured text which is a quality contribution . . . a very readable text."
John A. Feagin, Jr., MD Military Medicine March '83

NITROSTAT®
(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information.
A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;
N 0071-0571-13—Convenience Package.

OF PROTECTING
ITS OWN.

So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of label claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1] NITROSTAT... useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept, Parke-Davis.

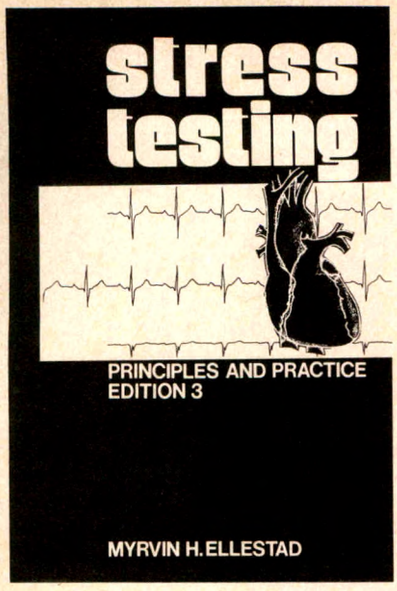
Improve your skill in stress testing with



Ellestad's **STRESS TESTING: Principles and Practice,** *New* 3rd Edition

The classic text on stress testing is now available in an expanded and comprehensively revised new 3rd Edition. Painstakingly up-dated so that every discussion brings you today's most current insights and advice, Dr. Ellestad's book has expanded into several new and critically important areas.

For the first time, complete chapter-long discussions focus on exercise stress testing after myocardial infarction, stress testing after surgical intervention and coronary angioplasty, rhythm and conduction disturbances in stress testing, stress testing in women, chest pain and normal coronary arteries, blood pressure measurement during exercise, and sports medicine and rehabilitation. Significant changes in medical knowledge are also reflected in the discussion of ischemia in asymptomatic subjects, and in the coverage of indications, contraindications, risks and safety factors as well.

Take this opportunity to reserve your copy of this vital, enjoyable, and informative medical classic.

By **Myrvin H. Ellestad,** MD, Chief, Division of Cardiology, Memorial Hospital Medical Center of Long Beach; Clinical Professor of Medicine, University of California, Irvine. About 545 pages, 200 ill. Ready November 1985. About $45.00.

Table of Contents:

1. History of Stress Testing
2. Cardiovascular and Pulmonary Response to Exercise
3. Extracardiac Effects of Exercise
4. Physiology of Cardiac Ischemic
5. Indications
6. Contraindications, Risks and Safety Precautions
7. Parameters
8. Stress Testing Protocol
9. Memorial Hospital Protocol
10. Exercise Stress Testing after Myocardial Infarction
11. Stress Testing after Surgical Intervention and Coronary Angioplasty
12. ECG Patterns and Their Significance
13. Rhythm and Conduction Disturbances in Stress Testing
14. Predictive Implications
15. Stress Testing in Women
16. Chest Pain and Normal Coronary Arteries
17. Blood Pressure Measurement During Exercise
18. Ischemia in Asymptomatic Subjects
19. Sports Medicine and Rehabilitation
20. Pediatric Stress Testing
21. Nuclear Stress Testing
22. Metabolic Abnormalities and Drugs
23. Computers

A DOUBLE-SIZE VOLUME **VALVULAR HEART DISEASE: Comprehensive Evaluation and Management**

This new exhaustive issue of Cardiovascular Clinics features the dramatic changes surrounding **Valvular Heart Disease** occurring during the past 10-15 years. In a double-size volume, Drs. Frankl and Brest focus on four critically important areas of development. Part 1 presents the latest medical opinion of the changing causes and natural history of valvular heart disease. Part 2 covers diverse diagnostic methods, including laboratory diagnosis, non-invasive graphic imaging and scintigraphic evaluation. Part 3 provides indepth study of clinical features, pathophysiology and management of syndromes such as mitral valve prolapse, aortic valve disease in the elderly, combined valvular and coronary artery disease, etc. The final section of this indispensable book explores surgical intervention and patient management — you'll find timely advice on selecting prosthetic heart valves and assessing long-term prognosis following valvular heart surgery. Consult with 31 respected researchers and clinicians in this single source. Order your copy today.

Edited by **William S. Frankl,** MD, and **Albert N. Brest,** MD. 505 pp. About 300 ill. Ready November 1985. About $90.00.

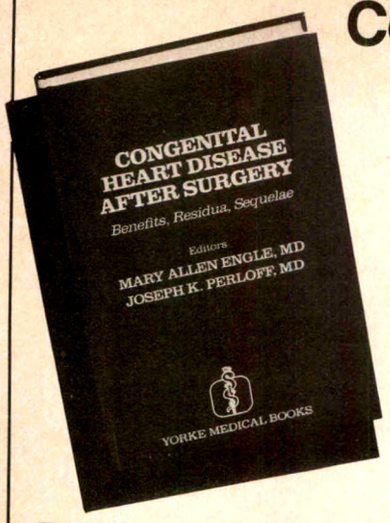
The Latest on the Postoperative Course of Congenital Heart Disease



Congenital Heart Disease After Surgery

Benefits, Residua, Sequelae

edited by **Mary Allen Engle, MD**
Joseph K. Perloff, MD

ISBN 0-914316-37-0, 438 pp., November 1983, $40.00

Thirty-five eminently respected medical researchers and clinicians have produced a book which provides in exhaustive detail much of the current thought, a good deal of which is based on several long-term follow-up studies, on the postoperative course of patients who have undergone surgery for congenital heart disease. It presents a realistic appraisal of problems that some individuals have after surgery for congenital heart disease and at the same time underscores the striking benefits derived from this cardiologic-surgical approach to treatment. This book will help physicians to deal effectively and knowledgeably with the rapidly expanding population of individuals who have had cardiac surgery because of congenital heart disease.

TABLE OF CONTENTS

PROLOGUE—Mary Allen Engle and Joseph K. Perloff
REMARKS—Helen B. Taussig

PART I
SURVEY

1. World survey of the common cardiac malformations: developmental error or genetic variant?
   Helen B. Taussig
2. Ten year and longer follow-up of 1000 consecutive children with cardiac malformations—the University of Minnesota experience
   Ray C. Anderson and James H. Moller

PART II
NONCYANOTIC CONGENITAL HEART DISEASE

3. Long-term follow-up of patients with malformations for which definitive surgical repair has been available for 25 years or more
   Dan G. McNamara and Larry A. Latson
4. Isolated coarctation of the aorta—long-term operative results
   Peter M. Steele, Valentin Fuster, Donald G. Ritter, Dwight C. McGoon
5. Late results after operations for left ventricular outflow tract obstruction
   Michael Jones, Glenn R. Barnhart, Andrew G. Morrow
6. Valvular residua and sequelae after operations for congenital heart disease
   William C. Roberts

PART III
CYANOTIC CONGENITAL HEART DISEASE

7. Late postoperative pulmonary vascular disease—clinical concerns
   William F. Friedman, Miriam F. Heiferman, Joseph K. Perloff
8. Long-term follow-up of patients born cyanotic
   Catherine A. Neill
9. Long-term effects of prosthetic materials
   Dwight C. McGoon
10. Second operations for pulmonary stenosis or insufficiency after repair of tetrology of Fallot
    Paul A. Ebert
11. Modified Mustard operation for simple and complex transposition of the great arteries—five-to-eleven year follow-up
    John E. O'Loughlin, Mary Allen Engle, William A. Gay Jr., Arthur A. Klein, Kathryn H. Ehlers, Aaron R. Levin

PART IV
POSTOPERATIVE FUNCTION

12. Sequelae of atriotomy on the endocardium, conduction system and coronary arteries
    Saroja Bharati and Maurice Lev
13. The myocardium, the conduction system, and general sequelae after surgery for congenital heart disase
    Saroja Bharati and Maurice Lev
14. Electrophysiologic residua and sequelae of surgery for congenital heart defects
    Victoria L. Vetter and Leonard N. Horowitz
15. Development and regression of increased ventricular mass
    Joseph K. Perloff
16. Ventricular performance in adults after operation for congenital heart disease
    Thomas P. Graham, Jr.

PART V
PSYCHOSOCIAL ASPECTS

17. Congenital heart disease and the quality of life
    James A. Manning
18. Pregnancy and its outcome in women with and without surgical treatment of congenital heart disease
    Ruth Whittemore, John C. Hobbins, Mary Allen Engle

PART VI
EPILOGUES

19. The pathologist
    Jesse E. Edwards
20. The pediatric cardiologist
    Alexander S. Nadas
21. The cardiac surgeon
    John W. Kirklin

Our OCC-7101A arrhythmia monitor has an updated pattern recognition capability which combines the best of multiple algorithms including feature extraction and correlation/template matching techniques. The result is highly accurate arrhythmia detection that has virtually eliminated those frustrating false alarms, helping the nursing staff make full use of precious time.

The arrhythmias that do occur are stored in memory capable of holding up to 1,000 events. And they can be recalled in four different ways to let the physician check them from the most suitable phase—he can recall critical waveform at a specific time based on the VPC trend, HR trend, itemized chronological marking or the alarm history for valuable clinical support.

Even with this level of sophistication, the advanced microprocessor still makes operation simple. The OCC-7101A 8-bed arrhythmia monitor has multi-function soft-keys just below the large 14″ display with their functions labelled on the adjacent screen. The push of a key recalls a trend or the tabulated alarm history while an arrow key lets the physician designate the particular time point he wants displayed.

Further, the compact package is equipped with a heat-writing recorder which produces a hard copy of ECG or recall waveform whenever necessary. You can also expand the system by adding an optional video printer to produce a hard copy of the screen image.

In tandem with the OGP-7101A or an existing central monitor, the OCC-7101A is a smart choice indeed for more effective critical care at a most affordable cost.

For details, call toll-free (800) 325-0283. In California (800) 423-2078.

Tired of false alarms?

This 8-bed arrhythmia monitor gives you today's most accurate arrhythmia detection.

And stores the most recent 1,000 events for instantaneous 4-way recall.

INFECTIOUS COMPLICATIONS OF NEOPLASTIC DISEASE

Controversies in Management

Edited by Arthur E. Brown, MD, and Donald Armstrong, MD
0-914316-43-5, approx. 400 pp., Oct. 1984, $40.00 casebound

About the book

Derived from a symposium sponsored by the Infectious Disease Service, Department of Medicine and the Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York City, and Cornell University Medical College, New York City, this book presents the latest thinking by international authorities, all of whom were invited to present findings in their area of expertise on the diagnosis, treatment, and prevention of various bacterial, fungal, viral, and parasitic infections presenting in patients with neoplastic disease.

This is not just another "proceedings" volume. Rather it is an edited work, with papers by investigators who submitted definitive preparations for publication. Furthermore, the authors take a strong position on their topics, ask probing questions and promote a stimulating forum of controversy.

The result is a concise, dynamic study that belongs in the professional library of every physician treating patients with neoplastic disease.

About the Editors

Arthur E. Brown, MD, is Assistant Attending Physician, Memorial Sloan-Kettering Cancer Center, and Assistant Professor of Medicine and Pediatrics, Cornell University Medical College.

Donald Armstrong, MD, is Attending Physician; Chief of Service; Director, Microbiology Laboratory, Memorial Sloan-Kettering Cancer Center, and Professor of Medicine, Cornell University Medical College

Table of Contents

PART I. DIAGNOSIS AND TREATMENT

Introduction and epidemiology
Neutropenia, fever, and infection
Significance of serum bactericidal activity in gram-negative bacillary bacteremia in patients with and without granulocytopenia
Approaching the controversies in antibacterial management of cancer patients
Can antibacterial therapy be discontinued in persistently febrile granulocytopenic cancer patients?
Quantitative blood cultures: a review of 52 years
Opportunistic fungal infections in patients with neoplastic disease
Chemotherapy of Systemic Mycoses
Viral infections in patients with neoplastic disease: diagnosis and therapy
Parasitic diseases in immunocompromised hosts

PART II. AIDS

Cluster of cases of the acquired immune deficiency syndrome: patients linked by sexual contact
Model-based approach to an analysis of a cluster pattern
Association between acquired immune deficiency syndrome and sexual contact: an analysis of the incidence pattern
Acquired immune deficiency syndrome (AIDS) trends in the United States
Assessment of therapy for Pneumocystis carinii pneumonia PCP Therapy Project Group

PART III. PREVENTION

Granulocyte transfusions
Leukocyte transfusions: thinking twice
Chemoprophylaxis of bacterial infections in granulocytopenic patients
Chemoprophylaxis of fungal infections
Legionnaires' Disease: aspects of nosocomial infection
Immunoprophylaxis and serotherapy of bacterial infections
Immunoprophylaxis of varicella-zoster infections
Current status of prophylaxis of infection with protected environments
Protected environments are discomforting and expensive and do not offer meaningful protection

"When the Ayerst rep told me it costs about 45¢ a day, I said you can stop right there."

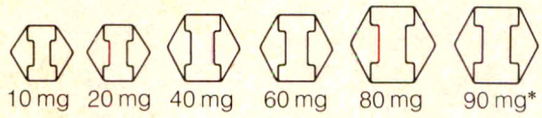
Most doctors are pleasantly surprised to learn that the average cost of daily therapy with the world's most widely used beta blocker is so little, not much more than the cost of a daily newspaper.

When it's INDERAL (propranolol hydrochloride) tablets you want for your hypertension patients, remember to specify Dispense As Written (DAW) or Do Not Substitute on your prescriptions. That way, you can always be assured they'll get INDERAL®. Please see next page for brief summary of prescribing information.

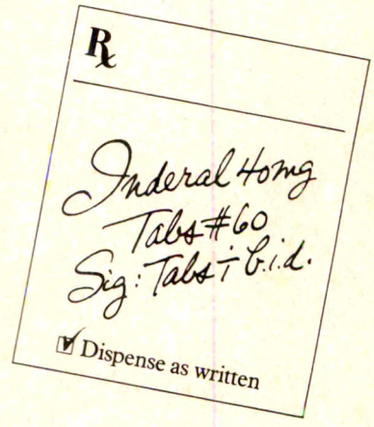
INDERAL®
(PROPRANOLOL HCl)
Small price to pay.

"When the Ayerst rep told me it costs about 45¢ a day, I said you can stop right there."

INDERAL® TABLETS
(PROPRANOLOL HCl)



10 mg 20 mg 40 mg 60 mg 80 mg 90 mg*



BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

INDERAL® (propranolol hydrochloride) Tablets

CONTRAINDICATIONS

INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma, 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS

General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL (propranolol hydrochloride) may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

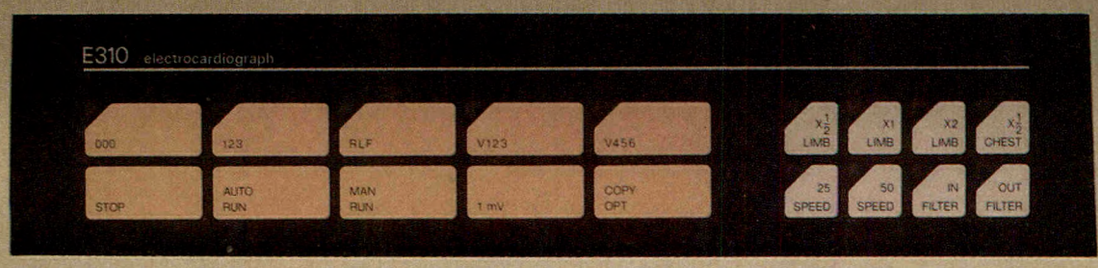
WHY PAY FOR MORE THAN YOU USE? BURDICK'S E 310



The high-volume E 310 from Burdick was designed to supply only the most-commonly used functions of a three-channel electrocardiograph. So you don't pay for all those features you never use.

Simplicity was also designed into the E 310. A glance at the control panel will tell you so. Just press Auto Run, and E 310 will run through all classical lead groups. Press the Copy touch pad, and E 310 will make diagnostically accurate copies of the last electrocardiogram — as many as you need.

So why pay for more 3-channel electrocardiograph than you use? E 310 is three-channel simplicity. Call for a demonstration.

E 310 — another value from the growing Burdick family.

If you like what you're reading, you'll love what you'll be watching

The American Journal of Cardiology does more than just print the best in authoritative articles on cardiovascular treatment. Now it puts them on videotape.

Hosted by Editor-in-Chief William C. Roberts, MD, *AJC Video Report* will feature lively, highly-visualized discussions with noted cardiovascular specialists and authors of the most important articles appearing each month in *The American Journal of Cardiology.* And it will extend the utility of the articles by exploring their application in clinical practice.

Each of the 45-minute videocassettes will feature a special guest panelist as well as the guest authors discussing:

• Coronary Heart Disease • Arrhythmias and Conduction Disturbances • Systemic Hypertension • Congestive Heart Failure • Valvular Heart Disease • Cardiomyopathy • Congenital Heart Disease • Cardiovascular Pharmacology and • Experimental Studies

AJC Video Report will be produced on a regular monthly basis starting January 1986. To order your subscription and make this important professional investment, just complete the card on the opposite page. If the card is missing, send your name, address (including zip code), medical specialty and videocassette format desired to: Joyce Sturges, *AJC Video Report,* The Yorke Medical Group, 875 Third Avenue, New York, N.Y. 10022. Or call (212) 605-9549.

The American Journal of Cardiology

The AJC in November 1960

WILLIAM C. ROBERTS, MD

The AJC in November 1960 contained 24 articles occupying 147 pages. This piece describes 5 articles.

Before antihypertension therapy, about 90% of patients with *systemic hypertension associated with papilledema* died within 1 year of diagnosis. Early articles on therapeutic effects of ganglionic blocking drugs described follow-up of patients for up to 3 years. Sokolow and Perloff[1] from San Francisco, California, described 5-year results of treatment of 26 patients with malignant hypertension (papilledema plus diastolic arterial pressure >120 mm Hg) with ganglionic blocking agents. Symptoms improved in all 26 patients and the diastolic pressures were reduced >20 mm Hg in 24 patients (92%). Papilledema disappeared in 19 patients (73%). Of 15 patients with poor renal function, improvement in renal function occurred in 7 (47%). The average survival of the 26 patients was 21 months; the 11 with good renal function before therapy survived an average of 39 months and the 15 with poor renal function an average of 8 months.

Shubin et al[2] from Los Angeles, California, described cardiovascular findings in 7 children with *sickle cell anemia* (blood hematocrits 18 to 27%). All 7 had normal pulmonary arterial pressures, normal or high cardiac indexes, and decreased systemic arterial oxygen saturations (77 to 89%). The heart rates at rest were 90 to 100 beats/min. All 7 had precordial systolic murmurs (grade 2/6 or greater), 5 had third heart sounds, all 7 had enlarged cardiac silhouettes on chest radiographs and 4 had abnormalities on electrocardiogram.

Hoffman and Lowrey[3] from Los Angeles, California, described electrocardiographic observations in 123 patients with *hyperthyroidism:* atrial fibrillation in 15 (12%); PR interval >0.20 second in 11 (9%); shortened QT interval in 18 patients (15%); ST-T abnormalities in 28 patients (23%); and heart rates at rest >100 beats/min in 46 patients (37%). The ST-T changes often were transient.

Baker et al[4] from Baltimore, Maryland, administered thyroid stimulating hormone (TSH), 25 mg/day intramuscularly, to each of 5 clinically euthyroid men for 4 or 5 successive days; 4 had electrocardiographic abnormalities during and immediately after the period of TSH stimulation. The abnormalities were those of increased irritability and altered repolarization.

Glover et al[5] from Philadelphia, Pennsylvania, described results of bilateral *ligation and division of the internal mammary artery* in 239 patients, of whom 219 were followed 12 to 30 months postoperatively. Of the 219 patients, 212 had angina pectoris (at rest in 115 patients) preoperatively, and 7 had no angina (recurring pulmonary edema in 4 and "serious arrhythmias" in 3). Of the 219 patients, 119 (54%) had electrocardiographic evidence of recent or healed myocardial infarction. At follow-up, 12 to 30 months postoperatively, 55 patients (25%) were markedly improved, 46 patients (21%) moderately improved, and 38 patients (17%) slightly improved. In 38 patients (17%) there was no improvement and 42 patients (20%) were dead. Only 24 patients (14%) changed in their clinical status 12 to 30 months postoperatively compared with their 1-month postoperative evaluation. Of course, objective evidence of decreased myocardial ischemia in their patients is lacking and coronary angiography was not available for their patients.

How Long Do Physicians Live?

In the USA today (1980 life tables), life expectancy from birth for white females is 78.1 years, for black females, 72.3 years, for white males, 70.7 years, and for black males, 63.7 years.[1] For persons who have reached age 25 years in the USA, an age reached by >95% of persons at the time of graduation from medical school, life expectancy is even greater. Thus, of persons reaching age 25 years, 54.5 additional years (to age 79.5) can be expected for white women and 49.5 additional years (to age 74.5) for black women, 47.8 additional years for white men (to age 72.8) and 41.7 additional years for black men (to age 66.7).[1]

Although physicians, of course, are included in these 1980 statistics, these expected ages are not reached by most USA graduates of USA medical schools. In the *Journal of the American Medical Association* each week is a column entitled "Obituaries." Included in it are the names of recently deceased physicians, their ages at death, the name of the medical school from which they graduated, frequently the American specialty board by which they were certified, and the date of their death. Their race is not included. For the 3 years 1981, 1982 and 1983 the age at death of the male and female physicians according to speciality was determined and the results of these tabulations are summarized in the accompanying table.

The table discloses 3 clear findings: (1) the average age at death of both the male and female physicians was below the national average for persons who had reached age 25 years; (2) the mean age of death of the female physicians was younger than that of their male counterparts; and (3) the mean age at death varied among the various subspecialties. The 9,705 male physicians lived a total of 689,184 years, an average of 71.0 years each; the 365 female physicians lived a total of 25,495 years, an average of 69.9 years each. Among the various subspecialties, those surviving the shortest periods on the average were neurosurgeons (58.9 years), anesthesiologists (58.9 years), family practitioners (62.4 years) and pathologists (63.9 years). The longest survivors on the average were those classified as both ophthalmologists and otolaryngologists (79.3 years), next those classified as otolaryngologists (76.7 years), and then those boarded in preventive medicine (74.4 years). The pediatricians survived on an average longer than did the internists (69.2 years vs 66.7 years). The specific numbers on survival for adult cardiologists, pediatric cardiologists, and cardiovascular surgeons are not available.

ROCHE

OVERLOAD

Reduce fluid volume and improve hemodynamics in CHF

Edema due to congestive heart failure often demands highly effective diuresis to reduce the fluid load on the failing heart. Bumex® (bumetanide/Roche) is the next generation in loop diuretic therapy for three powerful reasons. It moves out an unsurpassed volume of fluid and sodium, resulting in significant reductions in edema and right atrial and pulmonary artery wedge pressures.[1,2] It's almost completely absorbed through the GI tract, so it's easy to titrate.[3] And Bumex completes high-volume diuresis fast—within four hours at usual doses.[4,5] Your patients spend less time in diuresis, more time in normal activities.

Bumex has a good safety profile; however, as with all loop diuretics, Bumex, if given in excessive amounts, can lead to profound diuresis with water and electrolyte depletion, including hypokalemia. Serum electrolytes should be monitored periodically, especially in patients on low salt diets or those treated for prolonged periods or on high doses.

Bumex®
bumetanide/Roche
0.5-mg and 1-mg scored tablets/2-ml ampuls, 2-ml, 4-ml and 10-ml vials (0.25 mg/ml)

The next generation in loop diuretic therapy

2-ml ampuls, 2-ml, 4-ml and
10-ml vials (0.25 mg/ml)

BUMEX® (bumetanide/Roche)
Before prescribing, please consult complete product information, a summary of which follows:

WARNING: Bumex (bumetanide/Roche) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dosage schedule have to be adjusted to the individual patient's needs. (See under DOSAGE AND ADMINISTRATION in complete product information.)

INDICATIONS AND USAGE: Edema associated with congestive heart failure, hepatic and renal disease, including the nephrotic syndrome.
Almost equal diuretic response occurs after oral and parenteral administration of Bumex.
If impaired gastrointestinal absorption is suspected or oral administration is not practical, Bumex should be given by the intramuscular or intravenous route.
Successful treatment with Bumex following instances of allergic reactions to furosemide suggests a lack of cross-sensitivity.
CONTRAINDICATIONS: Anuria. Hypersensitivity and in patients in hepatic coma or in states of severe electrolyte depletion. Although Bumex can be used to induce diuresis in renal insufficiency, any marked increase in blood urea nitrogen or creatinine, or the development of oliguria during therapy of patients with progressive renal disease, is an indication for discontinuation of treatment.
WARNINGS: Dose should be adjusted to patient's needs. Excessive doses or too frequent administration can lead to profound water loss, electrolyte depletion, dehydration, reduction in blood volume and circulatory collapse with the possibility of vascular thrombosis and embolism, particularly in elderly patients.
Prevention of hypokalemia requires particular attention in patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis and ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, certain diarrheal states, or other states where hypokalemia is thought to represent particular added risks to the patients.
In patients with hepatic cirrhosis and ascites, sudden alterations of electrolyte balance may precipitate hepatic encephalopathy and coma. Treatment in such patients is best initiated in the hospital with small doses and careful monitoring of the patient's clinical status and electrolyte balance. Supplemental potassium and/or spironolactone may prevent hypokalemia and metabolic alkalosis in these patients.
In cats, dogs and guinea pigs, Bumex has been shown to produce ototoxicity. Since Bumex is about 40 to 60 times as potent as furosemide, it is anticipated that blood levels necessary to produce ototoxicity will rarely be achieved. The potential for ototoxicity increases with intravenous therapy, especially at high doses.
Patients allergic to sulfonamides may show hypersensitivity to Bumex.
PRECAUTIONS: Measure serum potassium periodically and add potassium supplements or potassium-sparing diuretics, if necessary. Periodic determinations of other electrolytes are advised in patients treated with high doses or for prolonged periods, particularly in those on low salt diets.
Hyperuricemia may occur. Reversible elevations of the BUN and creatinine may occur, especially with dehydration and in patients with renal insufficiency. Bumex may increase urinary calcium excretion.
Possibility of effect on glucose metabolism exists. Periodic determinations of blood sugar should be done, particularly in patients with diabetes or suspected latent diabetes.
Patients should be observed regularly for possible occurrence of blood dyscrasias, liver damage or idiosyncratic reactions.
Especially in presence of impaired renal function, use of parenterally administered Bumex should be avoided in patients to whom aminoglycoside antibiotics are also being given, except in life-threatening conditions.
Drugs with nephrotoxic potential and bumetanide should not be administered simultaneously.
Since lithium reduces renal clearance and adds a high risk of lithium toxicity, it should not be given with diuretics.
Probenecid should not be administered concurrently with Bumex.
Concurrent therapy with indomethacin not recommended.
Bumex may potentiate the effects of antihypertensive drugs, necessitating reduction in dosage.
Interaction studies in humans have shown no effect on digoxin blood levels.
Interaction studies in humans have shown Bumex to have no effect on warfarin metabolism or on plasma prothrombin activity.
Pregnancy: Bumex should be given to a pregnant woman only if the potential benefit justifies the potential risk to the fetus.
Bumetanide may be excreted in breast milk.
Pediatric Use: Safety and effectiveness below age 18 not established.
ADVERSE REACTIONS: Muscle cramps, dizziness, hypotension, headache and nausea, and encephalopathy (in patients with preexisting liver disease).
Less frequent clinical adverse reactions are weakness, impaired hearing, rash, pruritus, hives, electrocardiogram changes, abdominal pain, arthritic pain, musculoskeletal pain and vomiting.
Other clinical adverse reactions are vertigo, chest pain, ear discomfort, fatigue, dehydration, sweating, hyperventilation, dry mouth, upset stomach, renal failure, asterixis, itching, nipple tenderness, diarrhea, premature ejaculation and difficulty maintaining an erection.
Laboratory abnormalities reported are hyperuricemia, azotemia, hyperglycemia, increased serum creatinine, hypochloremia, hypokalemia, hyponatremia, and variations in CO_2 content, bicarbonate, phosphorus and calcium. Although manifestations of the pharmacologic action of Bumex, these conditions may become more pronounced by intensive therapy.
Diuresis induced by Bumex may also rarely be accompanied by changes in LDH, total serum bilirubin, serum proteins, SGOT, SGPT, alkaline phosphatase, cholesterol, creatinine clearance, deviations in hemoglobin, prothrombin time, hematocrit, platelet counts and differential counts. Increases in urinary glucose and urinary protein have also been seen.
DOSAGE AND ADMINISTRATION:
Oral Administration: The usual total daily dosage is 0.5 to 2.0 mg and in most patients is given as a single dose.
Parenteral Administration: Administer to patients (IV or IM) with GI absorption problem or who cannot take oral. The usual initial dose is 0.5 to 1 mg given over 1 to 2 minutes. If insufficient response, a second or third dose may be given at 2 to 3 hour intervals up to a maximum of 10 mg a day.
HOW SUPPLIED: *Tablets,* 0.5 mg (light green) and 1 mg (yellow), bottles of 100 and 500; Prescription Paks of 30; Tel-E-Dose® cartons of 100. Imprint on tablets: 0.5 mg—ROCHE BUMEX 0.5; 1 mg—ROCHE BUMEX 1.
Ampuls, 2 ml, 0.25 mg/ml, boxes of ten.
Vials, 2 ml, 4 ml and 10 ml, 0.25 mg/ml, boxes of ten.

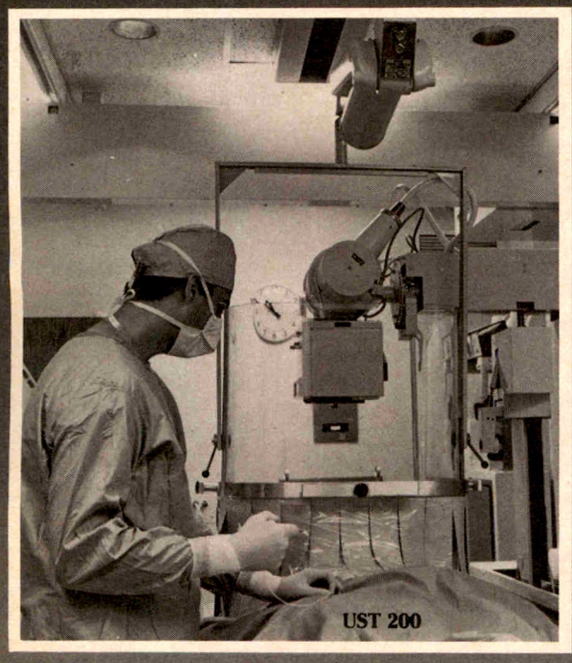
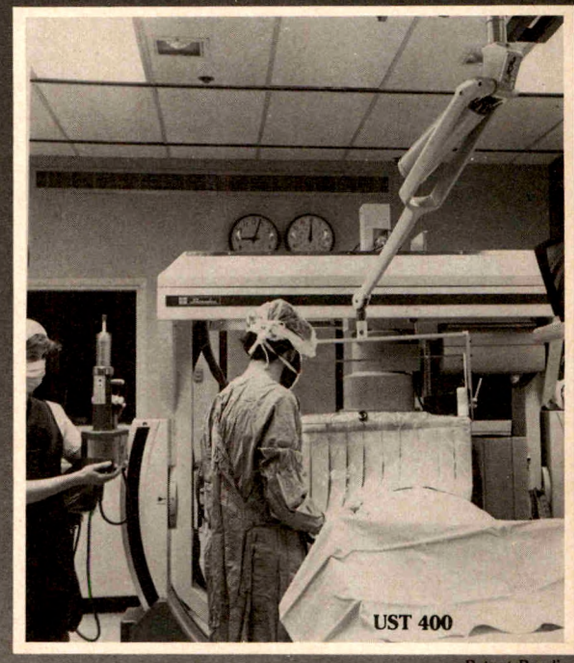
A Radiation Protective Shield for Interventional Radiology

"Provides protection from patient scatter during lengthy fluoroscopic procedures without interfering with the performance of the examination"





Patent Pending

The growing concern for radiation protection during modern theraputic fluoroscopic techniques for embolizations, abscess drainage, biliary drainage, cardiac catheterizations and other lengthy procedures has created a universal need for protective devices to shield harmful patient scatter.

The UST Interventional Shield, which is positioned close to the x-ray source, effectively reduces scatter radiation to less than 0.1 mr/hr, offering the maximum protection to the eyes, thyroid and complete upper torso of staff employees performing the procedure, while allowing total freedom of movement around the work area.

FEATURES:

- Lead acrylic patient observation panel (0.5mm to 1.0mm lead equivalency)
- Double split lead/vinyl patient forming curtain (1.0mm total lead equivalency) with disposable sterilized clear plastic sleeves
- Detachable aluminum positioning handles for autoclave use
- Dual pivotal locking devices
- Counter balanced ceiling suspension system and track assembly with 202 centimeters of horizontal travel

Also available for "C" and "U" - ARM type apparatus

UNITED SHIELDING TECHNOLOGY

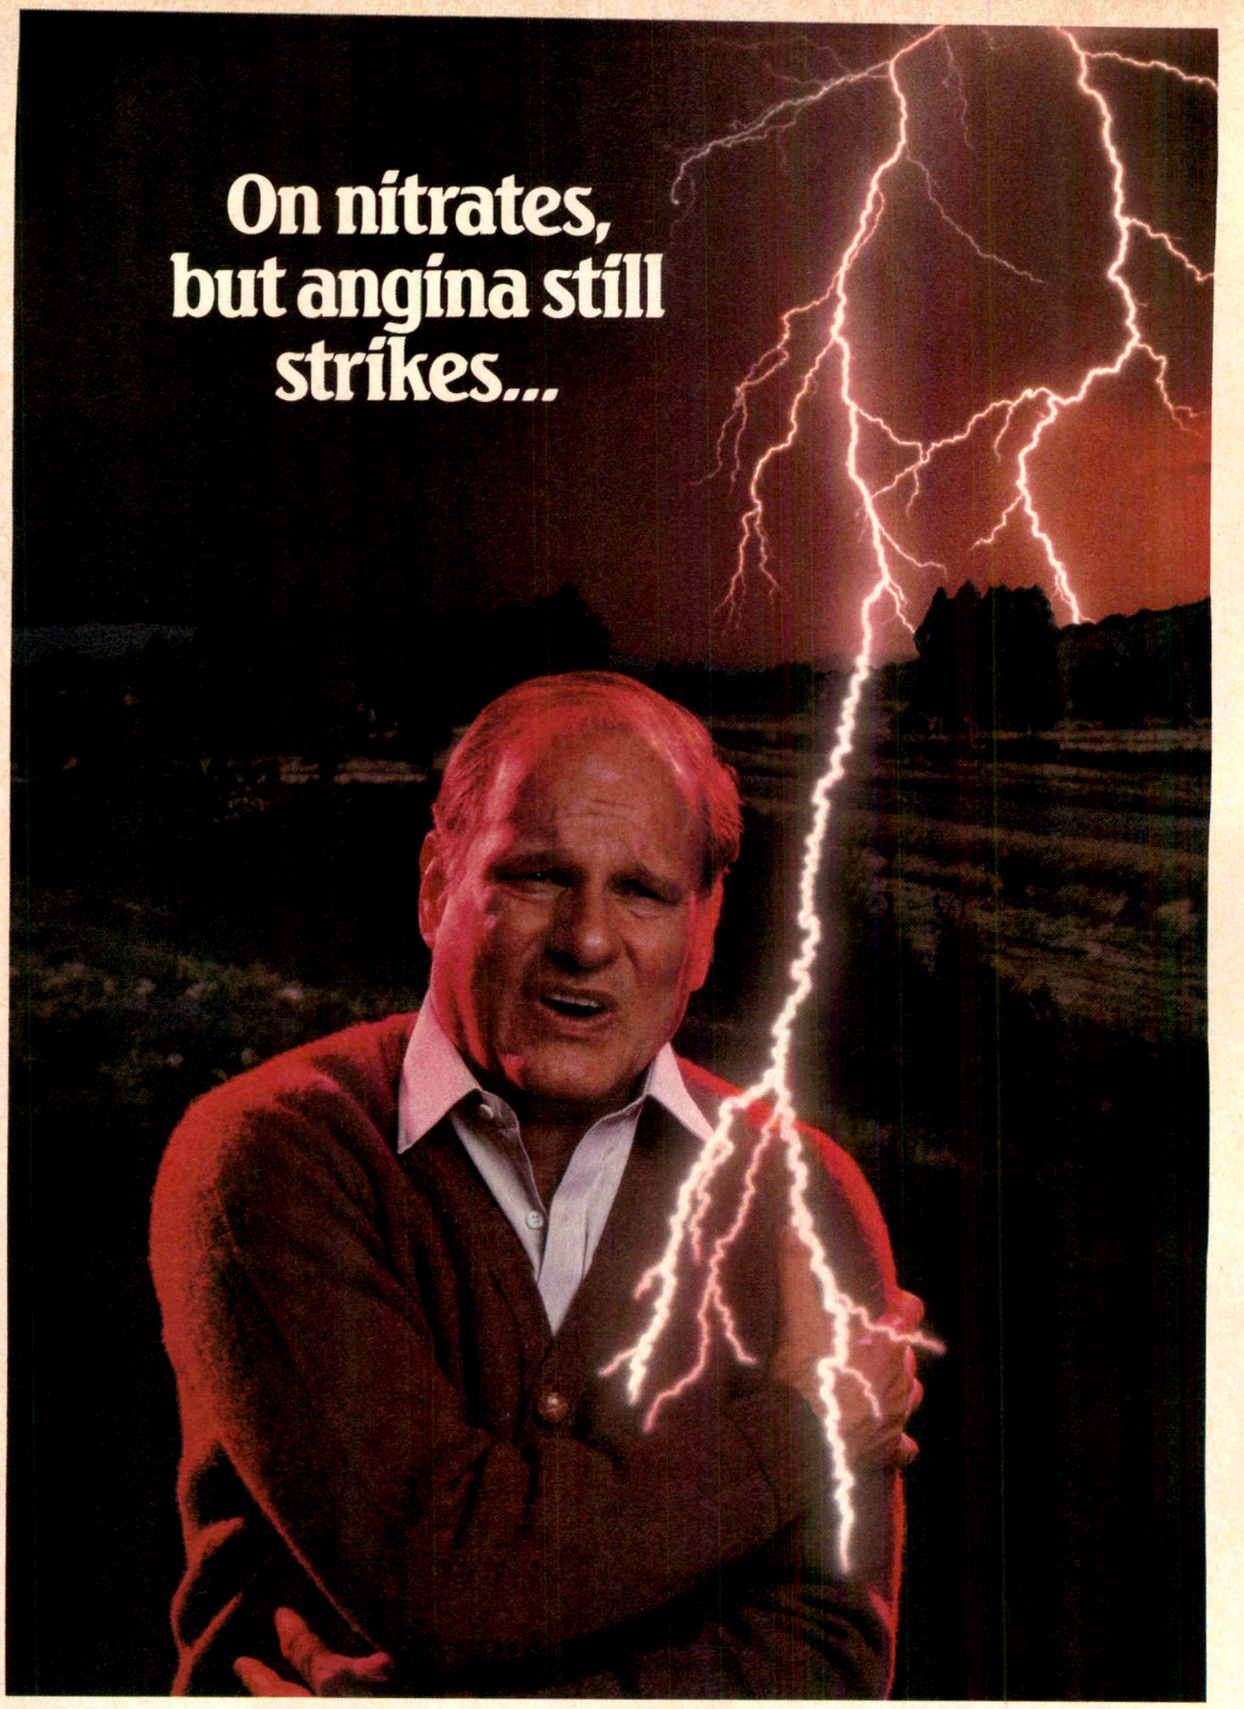
A1



On nitrates,
but angina still
strikes...

After a nitrate, add ISOPTIN®
(verapamil HCl/Knoll)

To protect your patients, as well as their quality of life, add Isoptin instead of a beta blocker.

First, Isoptin not only reduces myocardial oxygen demand by reducing peripheral resistance, but also increases coronary perfusion by preventing coronary vasospasm and dilating coronary arteries — both normal and stenotic. These are antianginal actions that no beta blocker can provide.

Second, Isoptin spares patients the beta-blocker side effects that may compromise the quality of life.

With Isoptin, fatigue, bradycardia and mental depression are rare. Unlike beta blockers, Isoptin can safely be given to patients with asthma, COPD, diabetes or peripheral vascular disease. Serious adverse reactions with Isoptin are rare at recommended doses; the single most common side effect is constipation (6.3%).

Cardiovascular contraindications to the use of Isoptin are similar to those of beta blockers: severe left ventricular dysfunction, hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no artificial pacemaker is present) and second- or third-degree AV block.

So, the next time a nitrate is not enough, add Isoptin... for more comprehensive antianginal protection without side effects which may cramp an active life style.

ISOPTIN. Added antianginal protection without beta-blocker side effects.

Please see brief summary on following page.

ISOPTIN®
(verapamil HCl/Knoll)
80 mg and 120 mg scored, film-coated tablets

Contraindications: Severe left ventricular dysfunction (see *Warnings),* hypotension (systolic pressure < 90 mm Hg) or cardiogenic shock, sick sinus syndrome (except in patients with a functioning artificial ventricular pacemaker), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction < 30% or moderate to severe symptoms of cardiac failure) and in patients with any degree of ventricular dysfunction if they are receiving a beta blocker. (See *Precautions.)* Patients with milder ventricular dysfunction should, if possible, be controlled with optimum doses of digitalis and/or diuretics before ISOPTIN is used. (Note interactions with digoxin under *Precautions.*) ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild and controlled by decrease in ISOPTIN dose). Elevations of transaminases with and without concomitant elevations in alkaline phosphatase and bilirubin have been reported. Such elevations may disappear even with continued treatment; however, four cases of hepatocellular injury by verapamil have been proven by rechallenge. Periodic monitoring of liver function is prudent during verapamil therapy. Patients with atrial flutter or fibrillation and an accessory AV pathway (e.g. W-P-W or L-G-L syndromes) may develop increased antegrade conduction across the aberrant pathway bypassing the AV node, producing a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion, which has been used safely and effectively after ISOPTIN. Because of verapamil's effect on AV conduction and the SA node, 1° AV block and transient bradycardia may occur. High grade block, however, has been infrequently observed. Marked 1° or progressive 2° or 3° AV block requires a dosage reduction or, rarely, discontinuation and institution of appropriate therapy depending upon the clinical situation. Patients with hypertrophic cardiomyopathy (IHSS) received verapamil in doses up to 720 mg/day. It must be appreciated that this group of patients had a serious disease with a high mortality rate and that most were refractory or intolerant to propranolol. A variety of serious adverse effects were seen in this group of patients including sinus bradycardia, 2° AV block, sinus arrest, pulmonary edema and/or severe hypotension. Most adverse effects responded well to dose reduction and only rarely was verapamil discontinued. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of excessive pharmacologic effects. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, close surveillance of vital signs and clinical status should be carried out. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patients should be carefully monitored to avoid over- or under-digitalization. ISOPTIN may have an additive effect on lowering blood pressure in patients receiving oral antihypertensive agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Clinical experience with the concomitant use of ISOPTIN and short- and long-acting nitrates suggest beneficial interaction without undesirable drug interactions. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C:* There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR < 50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%), elevations of liver enzymes have been reported. (See *Warnings.*) The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: ecchymosis, bruising, gynecomastia, psychotic symptoms, confusion, paresthesia, insomnia, somnolence, equilibrium disorder, blurred vision, syncope, muscle cramp, shakiness, claudication, hair loss, macules, spotty menstruation. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in round, scored, film-coated tablets containing either 80 mg or 120 mg of verapamil hydrochloride and embossed with "ISOPTIN 80" or "ISOPTIN 120" on one side and with "KNOLL" on the reverse side. Revised August, 1984. 2385

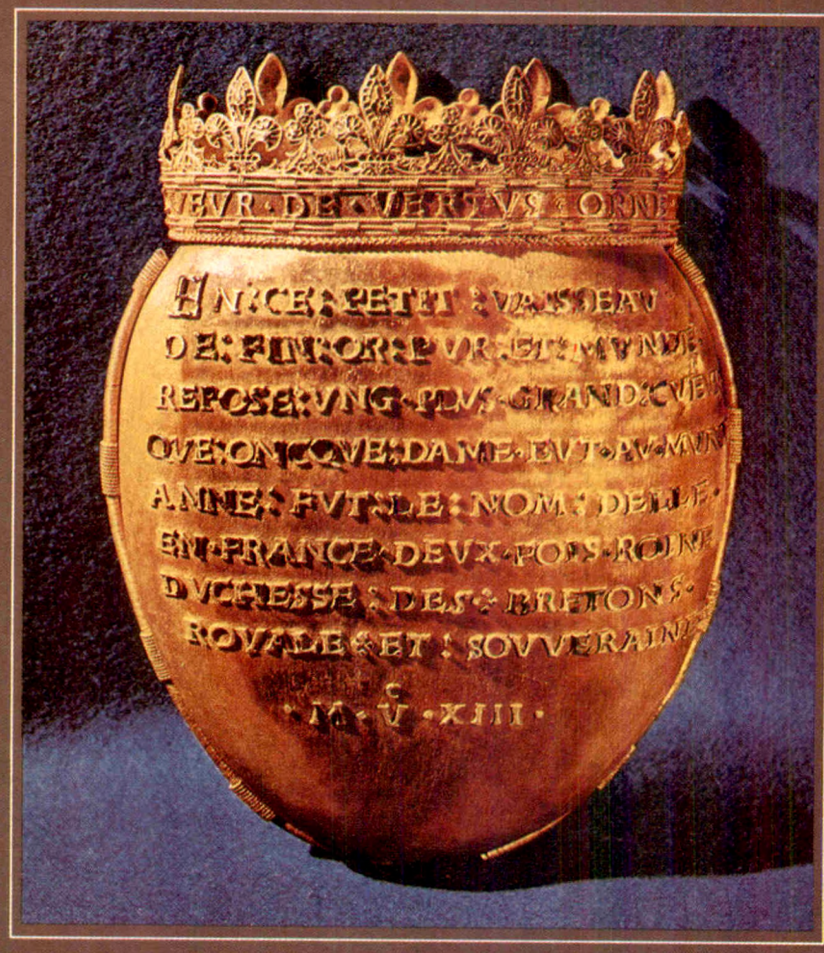
Participants will receive certificates for their records.

The Original

...the only clinically-tested dipyridamole



Reliquary, for the hear of Anne of Brittany
Museum of Nantes

Crafted entirely in gold, the reliquary bears an eloquent inscription extolling the virtue of Anne, Duchess of Brittany and Queen of France. The reliquary dates from 1513.

dipyridamole

Tablets of 25, 50 and 75 mg

Persantine®

The experienced dipyridamole

BRIEF SUMMARY

INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency of, or eliminate, anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.
PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.
ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.
DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy. Tablets of 25, 50 and 75 mg. For complete details, please see the full prescribing information.

The most important, best read annual publication on cardiology

What is CARDIOLOGY 1985?

- The fifth in an annual series to be published each summer—761 papers covered in this issue.
- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, **written,** not just edited, by those making outstanding contributions in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1985 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly accessible knowledge.

Reviews of previous editions

". . . recommend . . . to any reader interested in the literature of cardiology."
Irwin R. Callen, MD
JAMA

". . . It is more than merely a reference book, since it explains what to the average physician may be obscure . . . a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, MD
New York State Journal of Medicine

"I highly recommend this book as a reference for cardiologists and general internists who wish to review specific topics in the recent cardiology literature. The summaries are generally concise and well written and the choice of articles reviewed is superb and nicely indexed."
James L. Vacek, Major USAF, MC, FACC, FCCP
Military Medicine

"Dr. Roberts and his colleagues have done it again. . . . All in all, this is a remarkable tour de force of inestimable value to all physicians struggling to understand the heart and its problems."
David H. Spodick, MD
Practical Cardiology

Clinical Clues to MIXED ANGINA *No. 5*

The stairs seem steeper today

Most days she can climb the stairs with no difficulty. But today she was less than half-way up when an angina attack stopped her.

That's the unpredictability of MIXED ANGINA—vasoconstriction coexisting with fixed coronary lesion, to produce a critical reduction of myocardial blood flow.

And because vasoconstriction is an unpredictable event, ischemia and pain occur unpredictably:

- at varying levels of exercise
- at rest, or even during sleep
- upon exposure to cold
- under emotional stress
- diurnally, typically in the morning

PROCARDIA® (nifedipine) is a primary therapy for the patient with MIXED ANGINA. It prevents vasoconstriction in both large coronary arteries and coronary arterioles to maintain myocardial blood flow and oxygen supply. At the same time, PROCARDIA dilates peripheral arteries to reduce afterload and myocardial oxygen demand.

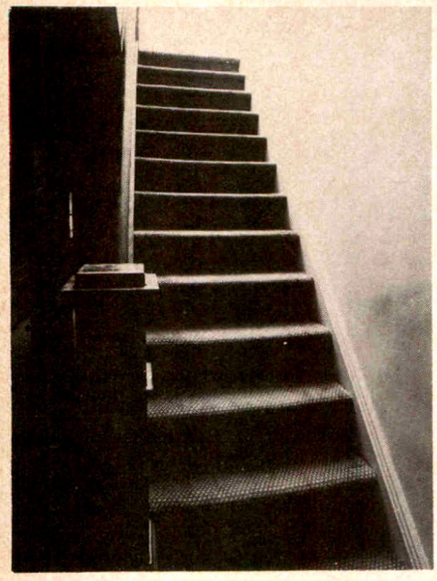
As a result, PROCARDIA can significantly reduce your patient's angina attack rate and need for nitroglycerin.[1]

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Primary Protection in
MIXED ANGINA

Please see PROCARDIA® (nifedipine) brief summary on next page.

The stairs seem steeper today



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PRIMARY PROTECTION IN MIXED ANGINA

Usual Effective Dosage: 30 to 60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level a a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration o severity of angina on starting PROCARDIA or at the time of dosage increases.

A Favorable Safety Profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

Reference:

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 106:644-652, 1983.

Brief Summary
PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA (nifedipine) therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some PROCARDIA patients. No clinical significance for these findings has been demonstrated.

Although PROCARDIA has been used safely in patients with renal dysfunction and has been reported to exert a beneficial effect in certain cases, rare, reversible elevations in BUN and serum creatinine have been reported in patients with pre-existing chronic renal insufficiency. The relationship to PROCARDIA therapy is uncertain in most cases but probable in some.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, or discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80% and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg per day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is initiated in a patient currently receiving cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryotoxic in rats, mice and rabbits. There are no adequate and well controlled studies in pregnant women. PROCARDIA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, shortness of breath, diarrhea, constipation, gastrointestinal cramps, flatulence, inflammation, joint stiffness, shakiness, jitteriness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, anemia, leukopenia, purpura, allergic hepatitis, gingival hyperplasia, and erythromelalgia. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Finally. A professional pocket-sized ECG that meets your exacting standards.

MICRO-TRACER® ECG PLUS

Introducing the first portable ECG that won't make you miss your office model!

A product of space-age miniaturization technology, MICRO-TRACER is a hospital-quality ECG offering greater versatility than any other portable ECG available today. ☐ Precise tracings indistinguishable from those produced by hospital single-channel ECGs. ☐ Phonocardiogram (PCG) tracings to detect the slightest murmurs, made possible by the accompanying DIF-STET,® a highly sensitive electronic stethoscope. ☐ Up to 12-vector capability. ☐ Continuous visual and audible monitoring with a continuous alarm triggered by bradycardia and tachycardia attacks. ☐ A heart-rate histogram for monitoring arrhythmias. ☐ With its optional modem, remote analyses and consultations can be obtained via the telephone. ☐ MICRO-TRACER, stethoscope and all required accessories, fit into a handsome, binocular-styled carrying case.

CLINICAL STRESS TESTING AT ITS BEST.

THE JUSTIFIABLE SYSTEM...

When your clinical needs dictate a sophisticated *and* cost-efficient diagnostic system for performing stress tests, Quinton's Q2000 System is the answer.

With the Q2000, you get:

- Powerful multi-processor hardware.
- Fast and accurate software analysis.
- Programmable flexibility.
- Diagnostic quality output.
- Long-term reliability.

PROGRAMMABILITY...

The easy-to-operate Q2000 enables you to program, modify and access up to 5 environments (procedures) and 9 protocols having up to 26 stages each.

THE DIAGNOSTIC EDGE...

ST Integral and Index, in addition to ST Slope and Level, provide higher sensitivity and specificity than slope and level alone. Your diagnostic confidence in tests that may otherwise produce marginal results is improved.

Also:

- Absolute Spatial Vector Velocity (ASVV) is used to identify aberrant beats, align normal beats for signal averaging and establish the isoelectric point.
- ST parameters may be measured from either J-junction or R-wave peak, and you program the measurement criteria.

The Q55 TREADMILL is included and provides 350-lb. patient capacity, 1–10 mph speed range, 0–25% grade range, and automatic calibration, self-test and trouble monitoring.

OTHER FEATURES...

- COMPREHENSIVE DISPLAYS—6 seconds of live ECG data, resting and current averaged beats, split screen freeze, tabular and graphic displays, continuous write from memory, digital displays of heart rate, ST parameters, and stage and time data.
- THERMAL CHART RECORDER—Programmable operation, AHA diagnostic quality traces, computer-averaged beats available.
- FINAL REPORT—An automatic summary of your patient's test data saves valuable time in report preparation.
- SERVICE AND MAINTENANCE—Fast response and the built-in maintenance programs keep the service call short.

For a detailed brochure, examples of ECG printouts and reports, and cost analysis information, call or write Quinton Instrument Company, 2121 Terry Avenue, Seattle, WA 98121-2791. 1-800-426-0347. Telex 3794094 In Washington state and Canada, call (206) 223-7373.

The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations.
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digoxin (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/or disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intense pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribing Information.

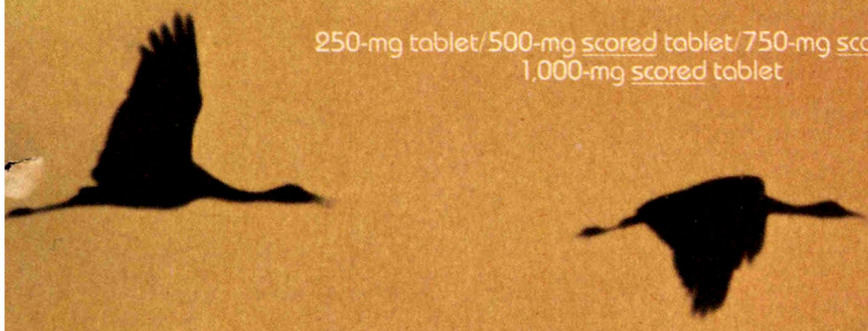
SUSTAINED RELEASE Procan® SR (PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet/500-mg scored tablet/750-mg scored tablet
1,000-mg scored tablet



Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

- Administered half as often as conventional oral procainamide
- Wide versatility in cardiac conditions
- Can be used concomitantly with digoxin
- Ideal maintenance therapy

Procan SR... the original sustained-release oral procainamide

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

LIBRARY

PROCAN® SR (procainamide hydrochloride tablets)
SUSTAINED RELEASE
Before prescribing, please see full prescribing information.
A Brief Summary follows.

> The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions, ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: Hypersensitivity to procainamide is an absolute contraindication. In this connection, cross-sensitivity to procaine and related drugs must be borne in mind.

Procainamide should not be administered to patients with complete atrioventricular heart block. It is also contraindicated in cases of second degree and third degree A-V nodal block unless an electrical pacemaker is operative.

It has been suggested that procainamide be contraindicated in patients with myasthenia gravis.

WARNINGS: Granulocytopenia may follow the use of procainamide, and deaths from sepsis have occurred. Leukocyte changes are most likely to occur during the first three months of therapy. During this time routine blood counts should be done at least every two weeks, and thereafter at longer intervals throughout maintenance procainamide therapy. Complaints of malaise and aches (a flu-type syndrome) are often reported in association with the granulocyte depression.

Patients should be instructed to report such symptoms promptly, as well as any soreness of mouth, throat or gums, unexplained fever, or symptoms of an upper respiratory tract infection. If these should occur and a complete blood count indicates a granulocyte depression, procainamide therapy should be discontinued immediately and appropriate treatment instituted. Recovery of leukocyte count usually occurs within a few weeks.

The incidence of granulocytopenia appears to be higher with procainamide sustained-release tablets than with standard tablets.

PRECAUTIONS: General—During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Serious hypotension can result from peripheral vasodilation and from decreases in cardiac output. At high plasma levels, procainamide may produce sinus tachycardia due to reflex sympathetic response to its hypotensive effect. Large doses may increase cardiac automaticity and can induce complete atrioventricular block, cardiac standstill, or ventricular extrasystoles that may proceed to ventricular fibrillation. These effects on the myocardium are reflected in the electrocardiogram: a widening of the QRS complex occurs most consistently; less regularly, the P-R and Q-T intervals are prolonged, and the QRS and T waves show some decrease in voltage.

Antinuclear antibodies (ANA) are often found in patients receiving long-term procainamide therapy. The induction of ANA appears to be independent of dosage. Patients with procainamide-induced increases in ANA titers may develop a syndrome resembling systemic lupus erythematosus (SLE). The mechanism of this syndrome is uncertain. Polyarthralgia, arthritic symptoms, and pleuritic pain are common symptoms; to a lesser extent fever, myalgia, skin lesions, pleural effusion, pericarditis, headache, fatigue, weakness, nausea and abdominal pain may occur. Rare cases of thrombocytopenia, Coombs' positive hemolytic anemia, increased SGOT, SGPT, and serum amylase have been reported which may be related to this SLE-like syndrome.

It is recommended that tests for systemic lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy. The drug should be discontinued if there is a rising ANA titer or clinical symptoms of SLE appear. The SLE-like syndrome may be reversible upon discontinuation of the drug. If discontinuation does not cause remission of the symptoms, corticosteroid therapy may be effective. If the SLE-like syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, corticosteroid suppressive therapy may be used concomitantly with procainamide.

Information for Patient—Practitioners should give the following information and instructions to patients receiving Procan SR.

1. Do not crush or chew these tablets. Swallow them whole.
2. Take this medicine exactly as directed by your doctor. Do not miss any doses and do not take more medicine than ordered. Do not stop taking this medicine without first checking with your doctor.
3. If you miss a dose and remember within one hour or so, take it as soon as possible. Then go back to your regular dosing schedule. Do not take double doses. If you have any questions about this, check with your doctor.
4. Report to your doctor any flu-type symptoms, such as malaise and aches, as well as any soreness of the mouth, throat or gums, unexplained fever, skin rash, unusual bleeding or bruising, symptoms that resemble arthritis, or symptoms of an upper respiratory tract infection.
5. Do not be concerned if you occasionally notice in your stool something that looks like a tablet. In Procan SR (procainamide hydrochloride tablets), the drug is 'held' in a wax core that has been specially designed to slowly release the drug for your body to absorb. When this process is completed the empty, nonabsorbable wax core, which looks nearly unchanged, is eliminated from your body.
6. Keep container tightly closed and store in a cool, dry place.

Laboratory Tests—Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals.

Routine blood counts are advisable during maintenance procainamide therapy. See WARNINGS for additional information.

Plasma concentrations of procainamide and NAPA should be monitored in patients with renal disease, hepatic disease, cardiac failure, or low cardiac output states.

Drug Interactions

1. **Antiarrhythmics:** Concurrent use with procainamide may result in additive cardiac effects and/or additive toxic effects.
2. **Anticholinergics:** Procainamide enhances the anticholinergic effects. Extreme caution must be exercised with such a combination.
3. **Anticholinesterases:** Procainamide antagonizes the effect of anticholinesterases in myasthenia gravis, and paralysis returns.
4. **Antihypertensives:** Procainamide may potentiate the hypotensive effects of thiazide diuretics and other antihypertensive agents. Adjustment of dosage may be required.
5. **Cimetidine:** It has been reported that the histamine H_2-antagonist cimetidine reduces renal clearance of procainamide and NAPA, resulting in higher plasma concentrations for longer durations. Caution should be exercised when administering these drugs concurrently, especially in the elderly, who have a reduced ability to clear all three. Dosage modification may be required.
6. **Neuromuscular Blocking Agents:** Procainamide potentiates the effects of skeletal muscle relaxants such as succinylcholine. It also may enhance or prolong the neuromuscular blocking activity of bacitracin, colistimethate, dihydrostreptomycin, gentamicin, gramicidin, kanamycin, neomycin, polymyxin B, streptomycin, and viomycin, producing respiratory depression.

Pregnancy—Pregnancy Category C. Animal reproduction studies have not been conducted with procainamide. It is also not known whether procainamide can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Procainamide should be given to a pregnant woman only if clearly needed.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when procainamide is administered to a nursing woman.

ADVERSE REACTIONS: Most frequent, especially with large oral doses:
1. Anorexia 2. Nausea 3. Vomiting 4. Diarrhea 5. Urticaria 6. Pruritus.

Less frequent: 1. Reactions in patients on long-term procainamide therapy: a. Antinuclear antibodies (ANA) b. Syndrome resembling systemic lupus erythematosus (SLE) (See PRECAUTIONS).

2. Hypersensitivity reactions: a. Angioneurotic edema b. Maculopapular rash c. Fever d. Eosinophilia e. Hypergammaglobulinemia.

Infrequent: 1. Granulocytopenia, sometimes resulting in death (See WARNINGS) 2. Convulsions 3. Psychosis with hallucinations 4. Confusion 5. Mental depression 6. Giddiness 7. Lightheadedness 8. Weakness 9. Bitter taste.

Rare: 1. Hypotension 2. A case was reported with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following a single dose of the drug.

OVERDOSAGE: Signs and symptoms of overdosage of procainamide include severe hypotension, ventricular fibrillation, widening of the QRS complex, junctional tachycardia, intraventricular conduction delay, oliguria, lethargy, confusion, nausea, and vomiting.

If ingestion is recent, gastric lavage or emesis may reduce absorption. Dopamine, phenylephrine or levarterenol may be helpful in reversing severe hypotensive responses.

Management of overdosage includes symptomatic treatment with ECG and blood pressure monitoring. Procainamide toxicity can usually be treated, if necessary, by administering vasopressors after adequate fluid volume replacement. Intravenous infusion of 1/6 molar sodium lactate injection reportedly reduces the cardiotoxic effects of procainamide.

The urinary elimination of procainamide is proportional to the glomerular filtration rate but is also affected by changes in urinary pH. Procainamide is relatively lipid-soluble as a free base, but the ionized form is not. Acid urine, therefore, leads to ion trapping of procainamide which enters the urine by passive diffusion from the plasma. Accordingly, renal clearance of procainamide can be considerably increased by maintaining a low urinary pH and high flow rates.

If procainamide toxicity causes severe hypotension and renal insufficiency, urinary elimination of procainamide and NAPA is decreased, and hemodialysis may be required. Hemodialysis significantly reduces the serum half-life of procainamide, and effectively removes procainamide and NAPA. Peritoneal dialysis is not effective.

It has been reported that one patient who ingested approximately 7 grams of procainamide hydrochloride recovered after treatment consisting of IV levarterenol, IV furosemide, attempted volume expansion with albumin, and hemodialysis. Also reported is the case of an elderly patient who recovered after ingestion of approximately 19 grams of procainamide hydrochloride. The patient was treated with IV isoproterenol and IV epinephrine. The latter report suggested that insertion of a ventricular pacing electrode is a reasonable precautionary measure in case high grade A-V block develops.

Storage Conditions—Protect from moisture. Store bottles below 30° C (86° F). Store unit-dose packages at controlled room temperature, 15°-30° C (59°-86° F). 0207G012
Caution: Federal law prohibits dispensing without prescription.

CONTENTS IN BRIEF

NOVEMBER 15, 1985 • VOLUME 56 • NUMBER 13

CORONARY HEART DISEASE

839 **Prediction of Functional Capacity and Use of Exercise Testing for Predicting Risk After Acute Myocardial Infarction.** Erling Birk Madsen, Elizabeth Gilpin, Staffan Ahnve, Hartmut Henning, and John Ross, Jr.

846 **Repeated Quantitative Angiograms in Coronary Arterial Aneurysm in Kawasaki Disease.** Hiroyuki Nakano, Ken Ueda, Akihiro Saito, and Keiko Nojima

852 **Identification of Best Electrocardiographic Leads for Diagnosing Myocardial Infarction by Statistical Analysis of Body Surface Potential Maps.** Fred Kornreich, Pentti M. Rautaharju, James Warren, Terrence J. Montague, and B. Milan Horacek

857 **Assessment of Left Ventricular Aneurysm Resectability by Two-Dimensional Echocardiography.** Cees A. Visser, Gerard Kan, Richard S. Meltzer, Ad C. Moulijn, George K. David, and Arend J. Dunning, *With the technical assistance of* Marga van Corler *and* Harry de Koning

861 **Relation Between Heart Rate and QT Interval in Excercise-Induced Myocardial Ischemia.** Massimo Romano, Teresa Di Maro, Giovanni Carella, Maria Rosaria Cotecchia, Giuseppe Ferro, and Massimo Chiariello

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

863 **Effects of Oral Amiodarone on Rate-Dependent Changes in Refractoriness in Patients with Wolff-Parkinson-White Syndrome.** Pedro Brugada and Hein J.J. Wellens

867 **Evaluation by Serial Electrophysiologic Studies of an Abbreviated Oral Loading Regimen of Amiodarone.** Eleanor E. Kennedy, Lynda E. Rosenfeld, Craig A. McPherson, and William P. Batsford

872 **Spontaneous Termination of Reciprocating Tachycardia Owing to Interaction of Dual Atrioventricular Nodal Pathways in Patients with an Accessory Pathway.** Karl-Heinz Kuck, Klaus-Peter Kunze, Michael Schlüter, and Walter Bleifeld

877 **Electrophysiologic Evaluation of the Antiarrhythmic Effects of N-Acetylprocainamide for Ventricular Tachycardia Secondary to Coronary Artery Disease.** Jonathan Wynn, Dennis S. Miura, Vilma Torres, David Flowers, Deborah Keefe, Sharon Williams, and John C. Somberg

883 **Electropharmacologic Testing in Sustained Ventricular Tachycardia Associated with Coronary Heart Disease: Value of the Response to Intravenous Procainamide in Predicting the Response to Oral Procainamide and Oral Quinidine Treatment.** Daniel S. Oseran, Eli S. Gang, Mark E. Rosenthal, William J. Mandel, and Thomas Peter

887 **Spectrum of Antiarrhythmic Response to Encainide.** Henry J. Duff, Dan M. Roden, Edmund L. Carey, Theodore Wang, R. Kirby Primm, and Raymond L. Woosley

892 **Exercise-Induced Left Bundle Branch Block and Its Relation to Coronary Artery Disease.** Charles Vasey, Jacqueline O'Donnell, Stephen Morris, and Paul McHenry

CONGESTIVE HEART FAILURE

896 **Acute Effects of Digoxin on Total Systemic Vascular Resistance in Congestive Heart Failure Due to Dilated Cardiomyopathy: A Hemodynamic-Hormonal Study.** Hillel S. Ribner, Dominic A. Plucinski, Ann-Ming Hsieh, Dennis Bresnahan, Agostino Molteni, Joseph Askenazi, and Michael Lesch

CONGENITAL HEART DISEASE

905 **Response to the Valsalva Maneuver After the Fontan Procedure for Tricuspid Valve Atresia, Single Ventricle or Pulmonic Valve Atresia.** Samuel S. Gidding, Amnon Rosenthal, Albert P. Rocchini, and Macdonald Dick

910 **LETTERS**

INSTRUCTIONS TO AUTHORS on page 882

FOR HEART FAILURE
Available in 12.5 mg Tablets

GIVE THE GIFT OF MORE ACTIVE LIVING

CAPOTEN enhances patients' quality of life

☐ CAPOTEN relieves major heart failure symptoms, improves functional capacity.[1]

☐ Use CAPOTEN when symptoms persist despite digitalis and diuretic therapy.

ACE*INHIBITOR

CAPOTEN® (captopril tablets) IN HEART FAILURE†

YOUR FIRST CHOICE AFTER DIGITALIS AND DIURETICS

*Angiotensin Converting Enzyme

†CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis. In using CAPOTEN, consideration should be given to the risk of neutropenia/agranulocytosis. Use special precautions in patients with impaired renal function, collagen vascular disorders, or those exposed to other drugs (e.g., procainamide) known to affect the white cells or immune response. Evaluation of heart failure patients should always include assessment of renal function. See INDICATIONS, WARNINGS, and ADVERSE REACTIONS in the brief summary on the adjacent page.

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension—CAPOTEN (captopril) is indicated for the treatment of hypertension. Consideration should be given to the risk of neutropenia/agranulocytosis (see WARNINGS). CAPOTEN may be used as initial therapy for patients with normal renal function, in whom the risk is relatively low. In patients with impaired renal function, particularly those with collagen vascular disease, captopril should be reserved for those who have either developed unacceptable side effects on other drugs, or have failed to respond satisfactorily to drug combinations. CAPOTEN is effective alone and in combination with other antihypertensive agents, especially thiazide-type diuretics.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

WARNINGS: Neutropenia/Agranulocytosis—Neutropenia ($<1000/mm^3$) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine <1.6 mg/dL and no collagen disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during subsequent clinical experience. Of reported cases, about half had serum creatinine ≥ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors.

Evaluation of the hypertensive or heart failure patient should always include assessment of renal function. If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count $<1000/mm^3$) withdraw captopril and closely follow the patient's course.

Proteinuria—Total urinary proteins >1 g/day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy, patients with prior renal disease or those receiving captopril at doses >150 mg/day should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension—Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in mean blood pressure $>20\%$ were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function,* Hypertension—Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure—About 20% of patients develop stable elevations of BUN and serum creatinine $>20\%$ above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis*—A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction.

Surgery/Anesthesia—If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension: Patients on Diuretic Therapy*—Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics, and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity—In heart failure patients, vasodilators should be administered with caution.

Agents Causing Renin Release—Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity—The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium—Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. Use potassium-containing salt substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis—Indomethacin and other nonsteroidal anti-inflammatory agents may reduce the antihypertensive effect of captopril, especially in low renin hypertension.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category C—There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus. Captopril crosses the human placenta.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 7000 patients.

Renal—About 1 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic—Neutropenia/agranulocytosis have occurred (see WARNINGS). Anemia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic—Rash (usually maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depending on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 1000 patients—reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular—Hypotension may occur, see WARNINGS and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia—About 2 to 4 (depending on renal status and dose) of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, cough, alopecia, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with or without secondary cholestasis, have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of 100 (25 mg also available in bottles of 1000), and in UNIMATIC® single dose packs of 100 tablets.

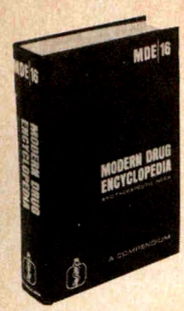
SQUIBB®

INNOVATORS IN CARDIOVASCULAR MEDICINE

© 1985 E. R. Squibb & Sons, Inc., Princeton, NJ 08540 525-518 Issued: September 1985

How thorough and unbiased is your drug reference?



If it's not the new 16th edition of MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Editor
Gertrude Dittus Gonzales, R.Ph., B.S., Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

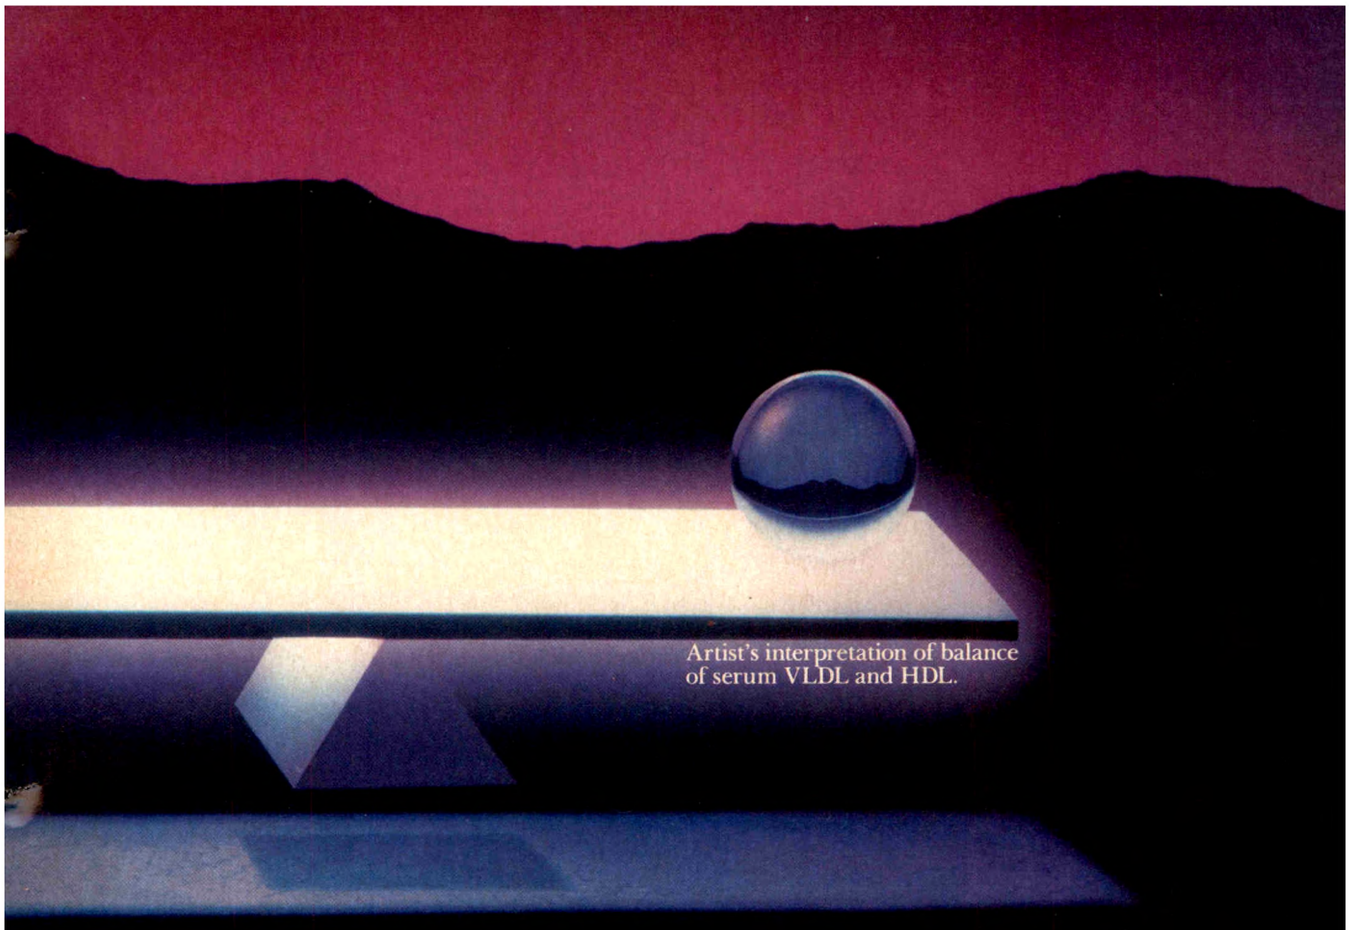
TWO-WAY LIPID REGULATOR

LOPID® *A Balanced Approach (gemfibrozil capsules, USP) 300 mg*

dicated for adult patients with high serum glycerides (type IV hyperlipidemia) who present risk of pancreatitis and who do not respond equately to diet.

linical trials show that Lopid vorably regulates the balance of rtain lipoproteins responsible r transport of serum lipids.

- Lowers elevated serum levels of triglyceride-rich very-low-density lipoproteins (VLDL) and, to a lesser extent, cholesterol-rich low-density lipoproteins (LDL)
- Favorably raises serum levels of high-density lipoproteins (HDL)
- Has a side effects profile similar to placebo and no significant abnormalities in clinical/laboratory evaluations
- Plus BID convenience

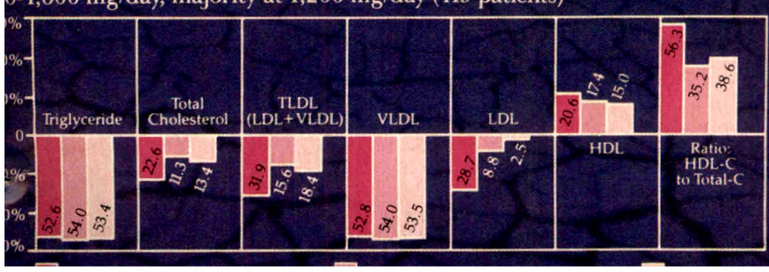


Artist's interpretation of balance of serum VLDL and HDL.

o Therapy of Certain Dyslipidemias

Lipid-regulating efficacy: pen-label phase of US multicenter study t end of 12 lunar months*[1]

erage percent change from baseline at doses ranging from 0-1,600 mg/day, majority at 1,200 mg/day (119 patients)†



Diet, exercise and weight loss are the first choice in therapy of lipid disorders.

*Visit every 4 weeks during long-term use of LOPID.

†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

1. Data on file, Medical Affairs Dept, Parke-Davis.

PARKE-DAVIS

Please see following page for brief summary of prescribing information.

TWO-WAY LIPID REGULATOR

LOPID®

(gemfibrozil capsules, USP) 300 mg

Before prescribing, please see full prescribing information.
A Brief Summary follows.

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO
		Total	VLDL	LDL	HDL	HDL Cholesterol / Total Cholesterol
IIa	−44%	−4.2%	−44.3%	− 5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	− 6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil capsules, USP) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (see WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings.)

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil capsules, USP) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in female or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria
Central Nervous System: headache, dizziness, blurred vision
Musculoskeletal: painful extremities
Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia
Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints
Central Nervous System: vertigo, insomnia, paresthesia, tinnitus
Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meals. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL CAPSULES, USP). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

CORONARY HEART DISEASE

839 **Prediction of Functional Capacity and Use of Exercise Testing for Predicting Risk After Acute Myocardial Infarction**

ERLING BIRK MADSEN, ELIZABETH GILPIN, STAFFAN AHNVE, HARTMUT HENNING, and JOHN ROSS, Jr.

Among 1,469 patients discharged after acute myocardial infarction (AMI), 466 patients (32%) underwent treadmill exercise testing close to the time of discharge. An ischemic exercise test response (ST-segment depression or angina) could not be predicted from historical or clinical variables. Good functional capacity (more than 4 METs) could be predicted using age and resting ST-segment changes, and among patients predicted to have a functional capacity of more than 4 METs, only 15% actually experienced low functional capacity on testing. Multivariate analysis of exercise test variables for predicting risk within 1 year selected only functional capacity, and this variable identified a large group of patients (72%) with very low risk of death and new AMI (less than 2%) and a high risk group of patients (29%) with 18% risk of death or new AMI.

846 **Repeated Quantitative Angiograms in Coronary Arterial Aneurysm in Kawasaki Disease**

HIROYUKI NAKANO, KEN UEDA, AKIHIRO SAITO, and KEIKO NOJIMA

To adequately manage patients with Kawasaki disease, the extent of associated coronary aneurysms was classified as follows: grade 0—no significant enlargement of the coronary artery; grade I—localized coronary aneurysms, with a maximum diameter of less than 4.0 mm; grade II—moderate-sized aneurysms, with a maximal diameter between 4.0 and 8.0 mm; and grade III—giant coronary aneurysms, with the maximal diameter greater than 8.0 mm. Most mild coronary aneurysms regressed to normal within a short time. The course of grade II aneurysms varied, depending on initial angiographic coronary size, but they eventually became reduced in size. In contrast, grade III aneurysms usually progressed into obstructive or stenotic coronary lesions. The current grading of severity of coronary artery disease may provide useful criteria to predict the prognosis of patients with Kawasaki disease.

852 **Identification of Best Electrocardiographic Leads for Diagnosing Myocardial Infarction by Statistical Analysis of Body Surface Potential Maps**

FRED KORNREICH, PENTTI M. RAUTAHARJU, JAMES WARREN, TERRENCE J. MONTAGUE, and B. MILAN HORACEK

A critical practical problem in body surface potential map analysis is the selection of optimal subsets of leads and features for diagnostic classification. Multivariate analysis was performed on 120-lead data from 184 normal subjects and 177 patients with myocardial infarction in order to identify leads and features for optimal diagnostic classification. Several areas on the map, most of which were located outside the precordial region, contained leads with important discriminant features. Six features (mostly ST-T measurements) from 3 locations—right subclavicular area, left posterior axillary region and left leg—correctly identified 95% of normal subjects and 95% of patients with myocardial infarction. The same number of features from the standard 12-lead electrocardiogram yielded 95% and 88%, respectively. It is concluded that leads outside the conventional chest locations contain important diagnostic information that can be extracted by the presented method.

857 **Assessment of Left Ventricular Aneurysm Resectability by Two-Dimensional Echocardiography**

CEES A. VISSER, GERARD KAN, RICHARD S. MELTZER, AD C. MOULIJN, GEORGE K. DAVID, and AREND J. DUNNING, *With the technical assistance of* MARGA van CORLER *and* HARRY de KONING

Two-dimensional echocardiography was performed in 56 patients undergoing aneurysmectomy to determine an index of the nonaneurysmal or residual myocardium. The end-diastolic length of normally moving endocardium of the 2 opposite walls in the apical 2- and 4-chamber view, and apical long-axis view was expressed as a fraction

Continued on page A12

of the end-diastolic length of the left ventricle. The index was assessed by averaging the 6 ratios obtained. With 1 exception, this index sharply separated survivors from nonsurvivors. The lower limit to survive aneurysmectomy was 40%.

861 **Relation Between Heart Rate and QT Interval in Exercise-Induced Myocardial Ischemia**

MASSIMO ROMANO, TERESA Di MARO, GIOVANNI CARELLA, MARIA ROSARIA COTECCHIA, GIUSEPPE FERRO, and MASSIMO CHIARIELLO

The relation between heart rate and QT interval during dynamic upright exercise was assessed in 18 control subjects and in 23 patients with coronary stenoses and exercise-induced myocardial ischemia. A significant negative linear correlation was found in both groups; the correlation coefficient was higher in control subjects than in the group with coronary artery disease (CAD) ($r = -0.78$ and -0.64, respectively), probably as a consequence of the nonhomogeneous response in CAD patients. The regression line had a flatter slope in patients with CAD, whereas a faster decrease of the QT increasing rate was seen in control subjects. This phenomenon may be related to an impairment of ischemic myocardium in responding to exercise-induced catecholamine release or to a direct effect of exercise-induced ischemic prolongation of myocardial tension.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

863 **Effects of Oral Amiodarone on Rate-Dependent Changes in Refractoriness in Patients with Wolff-Parkinson-White Syndrome**

PEDRO BRUGADA and HEIN J.J. WELLENS

The effects of oral amiodarone on rate-dependent behavior of the refractory periods during cardiac pacing were studied in 13 patients with the Wolff-Parkinson-White syndrome. Amiodarone produced a rate-dependent increase in refractoriness of the accessory pathway in anterograde direction in 5 patients and in retrograde direction in 3. The right atrial and right ventricular refractory periods continued to shorten significantly when the pacing rate was increased after amiodarone treatment. When these data were correlated with the mode of initiation and termination of tachycardia, a possible effect of the rate-dependent increase in refractoriness of the accessory pathway was observed in only 1 patient. Antiarrhythmic drugs should, ideally, produce a rate-dependent increase in refractoriness in reentrant circuits. This would facilitate prompt spontaneous termination of tachycardia by creating block for the circulating impulse. Further development of new antiarrhythmic drugs should include a search for components resulting in a reliable and predictable rate-dependent increase in refractoriness.

867 **Evaluation by Serial Electrophysiologic Studies of an Abbreviated Oral Loading Regimen of Amiodarone**

ELEANOR E. KENNEDY, LYNDA E. ROSENFELD, CRAIG A. McPHERSON, and WILLIAM P. BATSFORD

Serial evaluation of electrophysiologic variables was used in 25 patients with ventricular tachycardia (VT) to assess the adequacy of a 1-week oral loading regimen at 1,200 mg/day and to modify discharge dosing. During the initial week of loading, highly significant ($p < 0.001$) increases occurred in the AH interval, HV interval, AV nodal Wenckebach cycle length, ventricular refractory period and VT cycle length. After 2 months of maintenance therapy at 800 mg/day or less, as guided by electrophysiologic assessment, there was no additional change in any of the above variables except for an increase in VT cycle length. VT inducibility was not consistently affected. It is concluded that patients can be discharged after 1 week of oral amiodarone loading at 1,200 mg/day, and that modification of maintenance dosing by electrophysiologic assessment fosters steady perpetuation of cardiac amiodarone effect.

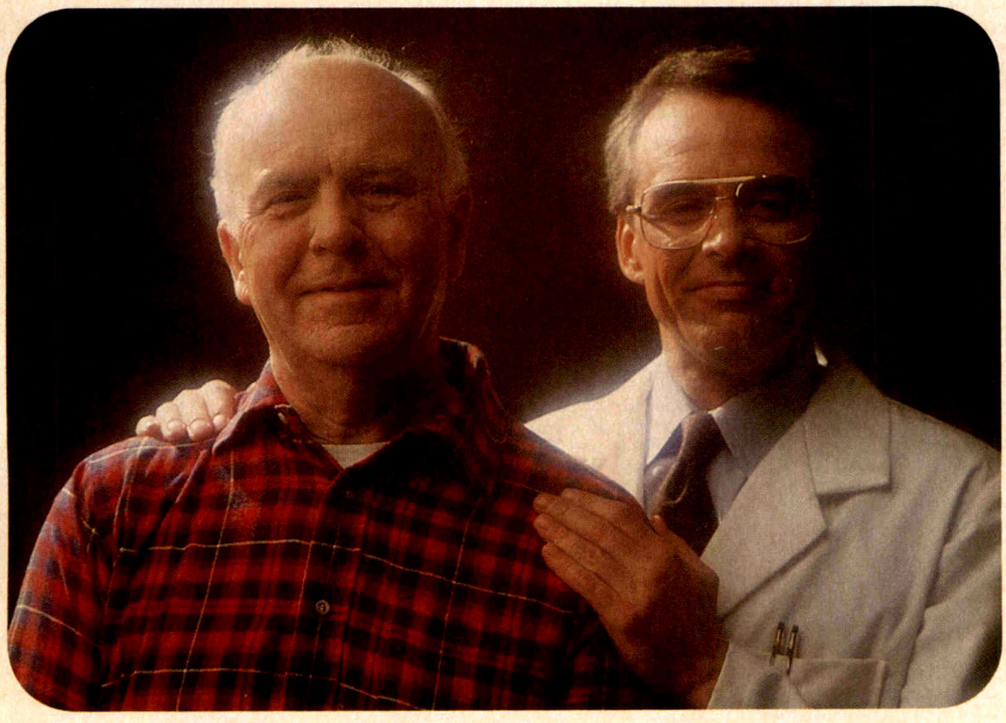
872 **Spontaneous Termination of Reciprocating Tachycardia Owing to Interaction of Dual Atrioventricular Nodal Pathways in Patients with an Accessory Pathway**

KARL-HEINZ KUCK, KLAUS-PETER KUNZE, MICHAEL SCHLÜTER, and WALTER BLEIFELD

In 7 of 125 patients with accessory atrioventricular (AV) pathways, the presence of dual AV nodal pathways was suggested by the mode of spontaneous termination of reciprocating tachycardia. Three types of tachycardia termination were observed. In 2 patients with antidromic tachycardia, termination was a result of AV nodal reentry. In 3 other patients with antidromic tachycardia, termination occurred after a sudden switch from a slow to a fast AV nodal pathway, resulting in conduction block within the AV reentrant circuit. In 2 patients with orthodromic tachycardia, termination was caused by the occurrence of an AV nodal echo beat. The interaction of dual AV nodal pathways within the reentrant circuit incorporating the accessory pathway always inhibited sustained reciprocating tachycardia.

Continued on page A15

SAFER FOR MANY PATIENTS



- Many common prescription and OTC drugs can cause variations in digoxin absorption.
- Lanoxicaps are more rapidly and completely absorbed to minimize these interactions.
- Less variability in absorption means less risk of over- or under-digitalization, and increased safety.

LANOXICAPS®

(digoxin solution in capsules)

0.05 mg, 0.1 mg, 0.2 mg strengths

100 μg (0.1 mg) I.D. Imprint B2C (yellow)
200 μg (0.2 mg) I.D. Imprint C2C (green)

Brief Summary of Prescribing Information

Before using Lanoxicaps® (digoxin solution in capsules), the physician should be thoroughly familiar with the basic pharmacology of this drug as well as its drug interactions and its indications and usage.

CONTRAINDICATIONS: Digitalis glycosides are contraindicated in ventricular fibrillation. Any untoward effect requiring permanent discontinuation of other digitalis preparations usually constitutes a contraindication to digoxin. Hypersensitivity to digoxin itself is a contraindication to its use. Allergy to digoxin, though rare, does occur. It may not extend to all such preparations, and another digitalis glycoside may be tried with caution.

WARNINGS: The use of digoxin or other digitalis glycosides in the treatment of obesity is unwarranted and dangerous.

It is recommended that digoxin in soft capsules be administered in divided daily doses to minimize any potential adverse reactions. Where compliance is considered a problem, single daily dosing may be appropriate (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Anorexia, nausea, vomiting and arrhythmias may accompany heart failure or may be indications of digitalis intoxication. Clinical evaluation of the cause of these symptoms should be attempted before further digitalis administration.

Patients with renal insufficiency require smaller than usual maintenance doses of digoxin (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. Relatively low loading and maintenance doses and concomitant use of antihypertensive drugs may be necessary. Careful monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with severe carditis, such as carditis associated with rheumatic fever or viral myocarditis, are especially sensitive to digoxin-induced disturbances of rhythm.

Newborn infants display considerable variability in their tolerance to digoxin. Premature and immature infants are particularly sensitive, and dosage must not only be reduced but must be individualized according to their degree of maturity.

Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS:

General: Digoxin toxicity develops more frequently and lasts longer in patients with renal impairment because of the decreased excretion of digoxin. Therefore, dosage requirements will be decreased in patients with moderate to severe renal disease (see DOSAGE AND ADMINISTRATION section in complete prescribing information). More time is required to achieve an initial or new steady-state concentration in patients with renal impairment than in patients with normal renal function.

In patients with hypokalemia, toxicity may occur despite serum digoxin concentrations within the "normal range", because potassium depletion sensitizes the myocardium to digoxin. Hypokalemia may result from diuretic, amphotericin B or corticosteroid therapy, and from dialysis or mechanical suction of gastrointestinal secretions. It may also accompany malnutrition, diarrhea, prolonged vomiting, old age and long-standing heart failure. In general, rapid changes in serum potassium or other electrolytes should be avoided, and intravenous treatment with potassium should be reserved for special circumstances as described below (see TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGE section in complete prescribing information).

Calcium, particularly when administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. Hypercalcemia from any cause predisposes the patient to digitalis toxicity. Hypocalcemia can nullify the effects of digoxin in man; digoxin may be ineffective until serum calcium is restored to normal.

Hypomagnesemia may predispose to digitalis toxicity. If low magnesium levels are detected in a patient on digoxin, replacement therapy should be instituted.

Quinidine and verapamil cause a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. This rise appears to be proportional to the dose. Due to the considerable variability of these interactions, digoxin dosage should be carefully individualized.

Certain antibiotics may increase digoxin absorption in patients who convert digoxin to inactive metabolites in the gut (see Pharmacokinetics portion of the CLINICAL PHARMACOLOGY section in complete prescribing information). The magnitude of rise in serum digoxin concentration may be as much as two-fold in some cases. This interaction is significantly reduced if digoxin is given as Lanoxicaps.

Patients with acute myocardial infarction or severe pulmonary disease may be unusually sensitive to digoxin-induced disturbances of rhythm.

Atrial arrhythmias associated with hypermetabolic states (e.g. hyperthyroidism) are particularly resistant to digoxin treatment. Large doses of digoxin are not recommended as the only treatment of these arrhythmias and care must be taken to avoid toxicity. In hypothyroidism, the digoxin requirements are reduced. Digoxin responses in patients with compensated thyroid disease are normal.

Reduction of digoxin dosage may be desirable prior to electrical cardioversion to avoid induction of ventricular arrhythmias, but the physician must consider the consequences of rapid increase in ventricular response to atrial fibrillation if digoxin is withheld 1 to 2 days prior to cardioversion. If there is a suspicion that digitalis toxicity exists, elective cardioversion should be delayed. If it is not prudent to delay cardioversion, the energy level selected should be minimal at first and carefully increased in an attempt to avoid precipitating ventricular arrhythmias.

Incomplete AV block, especially in patients with Stokes-Adams attacks, may progress to advanced or complete heart block if digoxin is given.

In some patients with sinus node disease (i.e. Sick Sinus Syndrome), digoxin may worsen sinus bradycardia or sino-atrial block.

In patients with Wolff-Parkinson-White Syndrome and atrial fibrillation, digoxin can enhance transmission of impulses through the accessory pathway. This effect may result in extremely rapid ventricular rates and even ventricular fibrillation.

Digoxin may worsen the outflow obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS). Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with chronic constrictive pericarditis may fail to respond to digoxin. In addition, slowing of the heart rate by digoxin in some patients may further decrease cardiac output.

Patients with heart failure from amyloid heart disease or constrictive cardiomyopathies respond poorly to treatment with digoxin.

Digoxin is not indicated for the treatment of sinus tachycardia unless it is associated with heart failure.

Digoxin may produce false positive ST-T changes in the electrocardiogram during exercise testing.

Intramuscular injection of digoxin is extremely painful and offers no advantages unless other routes of administration are contraindicated.

Drug Interactions: Potassium-depleting *corticosteroids* and *diuretics* may be major contributing factors to digitalis toxicity. *Calcium*, particularly if administered rapidly by the intravenous route, may produce serious arrhythmias. *Quinidine* and *verapamil* cause a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. Certain *antibiotics* increase digoxin absorption in patients who inactivate digoxin by bacterial metabolism in the lower intestine, so that digitalis intoxication may result. *Propantheline* and *diphenoxylate*, by decreasing gut motility, may increase digoxin absorption. *Antacids kaolin-pectin, sulfasalazine, neomycin, cholestyramine* and certain *anticancer drugs* may interfere with intestinal digoxin absorption, resulting in unexpectedly low serum concentrations. *Thyroid* administration to a digitalized, hypothyroid patient may increase the dose requirement of digoxin. Concomitant use of digoxin and *sympathomimetics* increases the risk of cardiac arrhythmias because both enhance ectopic pacemaker activity. *Succinylcholine* may cause a sudden extrusion of potassium from muscle cells, and may thereby cause arrhythmias in digitalized patients. Although β adrenergic blockers or calcium channel blockers and digoxin may be useful in combination to control atrial fibrillation, their additive effects on AV node conduction can result in complete heart block.

Carcinogenesis, Mutagenesis, Impairment of Fertility: There have been no long-term studies performed in animals to evaluate carcinogenic potential.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Digoxin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Caution should be exercised when digoxin is administered to a nursing woman.

ADVERSE REACTIONS: The frequency and severity of adverse reactions to digoxin depend on the dose and route of administration, as well as on the patient's underlying disease or concomitant therapies (see PRECAUTIONS section). The overall incidence of adverse reactions has been reported as 5 to 20%, with 15 to 20% being considered serious (1 to 4% of patients receiving digoxin). Cardiac toxicity accounts for about one-half, gastrointestinal disturbances for about one-fourth, and CNS and other toxicity for about one-fourth of these adverse reactions.

Adults:

Cardiac—Unifocal or multiform ventricular premature contractions, especially in bigeminal or trigeminal patterns, are the most common arrhythmias associated with digoxin toxicity in adults with heart disease. Ventricular tachycardia may result from digitalis toxicity. Atrioventricular (AV) dissociation, accelerated junctional (nodal) rhythm and atrial tachycardia with block are also common arrhythmias caused by digoxin overdosage. Excessive slowing of the pulse is a clinical sign of digoxin overdosage. AV block (Wenckebach) of increasing degree may proceed to complete heart block.

Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac disturbances.

Gastrointestinal—Anorexia, nausea, vomiting and less commonly diarrhea are common early symptoms of overdosage. Uncontrolled heart failure may also produce such symptoms.

CNS—Visual disturbances (blurred or yellow vision), headache, weakness, apathy and psychosis can occur.

Other—Gynecomastia is occasionally observed.

Infants and Children: Toxicity differs from the adult in a number of respects. Anorexia, nausea, vomiting, diarrhea and CNS disturbances may be present but are rare as initial symptoms in infants. Cardiac arrhythmias are more reliable signs of toxicity. Digoxin in children may produce any arrhythmia. The most commonly encountered are conduction disturbances or supraventricular tachyarrhythmias, such as atrial tachycardia with or without block, and junctional (nodal) tachycardia. Ventricular arrhythmias are less common. Sinus bradycardia may also be a sign of impending digoxin intoxication, especially in infants, even in the absence of first degree heart block. Any arrhythmia or alteration in cardiac conduction that develops in a child taking digoxin should initially be assumed to be a consequence of digoxin intoxication.

877 Electrophysiologic Evaluation of the Antiarrhythmic Effects of N-Acetylprocainamide for Ventricular Tachycardia Secondary to Coronary Artery Disease

JONATHAN WYNN, DENNIS S. MIURA, VILMA TORRES, DAVID FLOWERS, DEBORAH KEEFE, SHARON WILLIAMS, and JOHN C. SOMBERG

N-acetylprocainamide (NAPA), an active antiarrhythmic metabolite of procainamide, was studied in 12 patients with coronary artery disease who presented with a cardiac arrest or documented sustained ventricular tachycardia (VT). Programmed electrical stimulation studies were performed in all 13 patients and all had inducible VT. Procainamide, 1,000 mg administered intravenously, was tested in 10 patients, and in 8 of them VT could still be provoked. NAPA, 18 mg/kg intravenously, prevented VT induction in 5 of 12 patients. Two patients have done well with long-term oral NAPA therapy, 1 died shortly after hospital discharge, and 2 patients had VT during Holter monitoring early in the therapeutic program. NAPA may be a useful antiarrhythmic drug for patients with VT.

883 Electropharmacologic Testing in Sustained Ventricular Tachycardia Associated with Coronary Heart Disease: Value of the Response to Intravenous Procainamide in Predicting the Response to Oral Procainamide and Oral Quinidine Treatment

DANIEL S. OSERAN, ELI S. GANG, MARK E. ROSENTHAL, WILLIAM J. MANDEL, and THOMAS PETER

Twenty patients with inducible sustained ventricular tachycardia were prospectively evaluated in order to determine whether the response to intravenous procainamide, as assessed by programmed ventricular stimulation, predicted the response to oral procainamide and oral quinidine administration. Overall, 6 patients (30%) responded favorably to intravenous procainamide, 10 (50%) responded to oral quinidine and 5 (25%) responded to oral procainamide. Fifteen patients (75%) had a concordant drug response for intravenous and oral procainamide. Ten patients (50%) had a concordant response for intravenous procainamide and oral quinidine. Fifteen patients (75%) had a concordant response for oral procainamide and oral quinidine. Thus, in patients with sustained ventricular tachycardia, the response to intravenous procainamide does not reliably predict the response to oral quinidine or oral procainamide. Serial day drug studies with these agents appear to be necessary.

887 Spectrum of Antiarrhythmic Response to Encainide

HENRY J. DUFF, DAN M. RODEN, EDMUND L. CAREY, THEODORE WANG, R. KIRBY PRIMM, and RAYMOND L. WOOSLEY

Thirty-seven patients were treated with encainide. Eight patients with sustained ventricular tachycardia and ischemic heart disease did not respond favorably to encainide, and more important, they frequently had paradoxical worsening of arrhythmias on encainide. In contrast, encainide was highly effective in patients with sustained ventricular tachycardia in the absence of old myocardial infarction. In patients with symptomatic, nonsustained ventricular tachycardia, encainide was also frequently effective independent of the underlying heart disease.

892 Exercise-Induced Left Bundle Branch Block and Its Relation to Coronary Artery Disease

CHARLES VASEY, JACQUELINE O'DONNELL, STEPHEN MORRIS, and PAUL McHENRY

The records of 2,584 consecutive patients who underwent both treadmill exercise testing and coronary cineangiography were reviewed to detemine the relation between exercise-induced, acceleration-dependent left bundle branch block (LBBB) and the presence of coronary artery disease (CAD). Rate-dependent LBBB during exercise was identified in 28 patients (1.1%), who were categorized according to their presenting symptoms. CAD was present in 7 of 10 patients who presented with classic angina pectoris, but 12 of 13 patients presenting with atypical chest pain had normal coronary arteries. All 10 patients in whom LBBB developed at a heart rate of 125 beats/min or greater were free of CAD. It is concluded that patients presenting with atypical chest pain in whom rate-dependent LBBB develops during treadmill exercise testing are significantly less likely to have CAD than patients who present with classic angina, and the onset of LBBB at a heart rate of 125 beats/min or greater is highly correlated with the presence of normal coronary arteries, regardless of patient presentation.

CONGESTIVE HEART FAILURE

896 Acute Effects of Digoxin on Total Systemic Vascular Resistance in Congestive Heart Failure Due to Dilated Cardiomyopathy: A Hemodynamic-Hormonal Study

HILLEL S. RIBNER, DOMINIC A. PLUCINSKI, ANN-MING HSIEH, DENNIS BRESNAHAN, AGOSTINO MOLTENI, JOSEPH ASKENAZI, and MICHAEL LESCH

The effects of the digitalis glycosides on systemic vascular resistance (SVR) in patients with congestive heart failure are controversial. Most investigators report a reduction in total SVR, which has been ascribed to withdrawal of elevated sympathetic tone. However, a decrease in SVR has not been found in all cases; plasma

Continued on page A16

norepinephrine levels have not previously been measured; and the roles of the renin-angiotensin-aldosterone and vasopressin systems are not known. Therefore, hemodynamic and hormonal changes were correlated after the intravenous administration of 1.0 mg of digoxin to 11 normotensive men in sinus rhythm with congestive heart failure due to dilated cardiomyopathy. Although significant decreases occurred in both plasma renin activity and plasma norepinephrine levels, total SVR did not decrease. Accordingly, improvement in cardiac function in this group appears to be a result of enhanced contractility without an associated reduction in impedance. Lack of concordance between SVR and changes in vasoactive hormones remains to be explained.

CONGENITAL HEART DISEASE

905 Response to the Valsalva Maneuver After the Fontan Procedure for Tricuspid Valve Atresia, Single Ventricle or Pulmonic Valve Atresia

SAMUEL S. GIDDING, AMNON ROSENTHAL, ALBERT P. ROCCHINI, and MACDONALD DICK

Valsalva maneuvers were performed during cardiac catheterization in 9 patients who had undergone a Fontan operation and in 10 control subjects. Patients in the Fontan group had higher right atrial pressure, lower cardiac index, lower stroke index and higher systemic vascular resistance than control subjects. Four Fontan patients had a normal 4-phase Valsalva response and 5 did not. Right atrial pressure was similar in normal and abnormal responders, whereas in the normal responders cardiac index and stroke index were higher and systemic vascular resistance was lower. Thus, cardiac output is a better predictor of a normal response to the Valsalva maneuver than right atrial pressure in patients after the Fontan procedure. A normal response to the supine Valsalva maneuver suggests a cardiac index greater than 2.4 liters/min/m^2 and stroke index greater than 31 ml/beat/m^2.

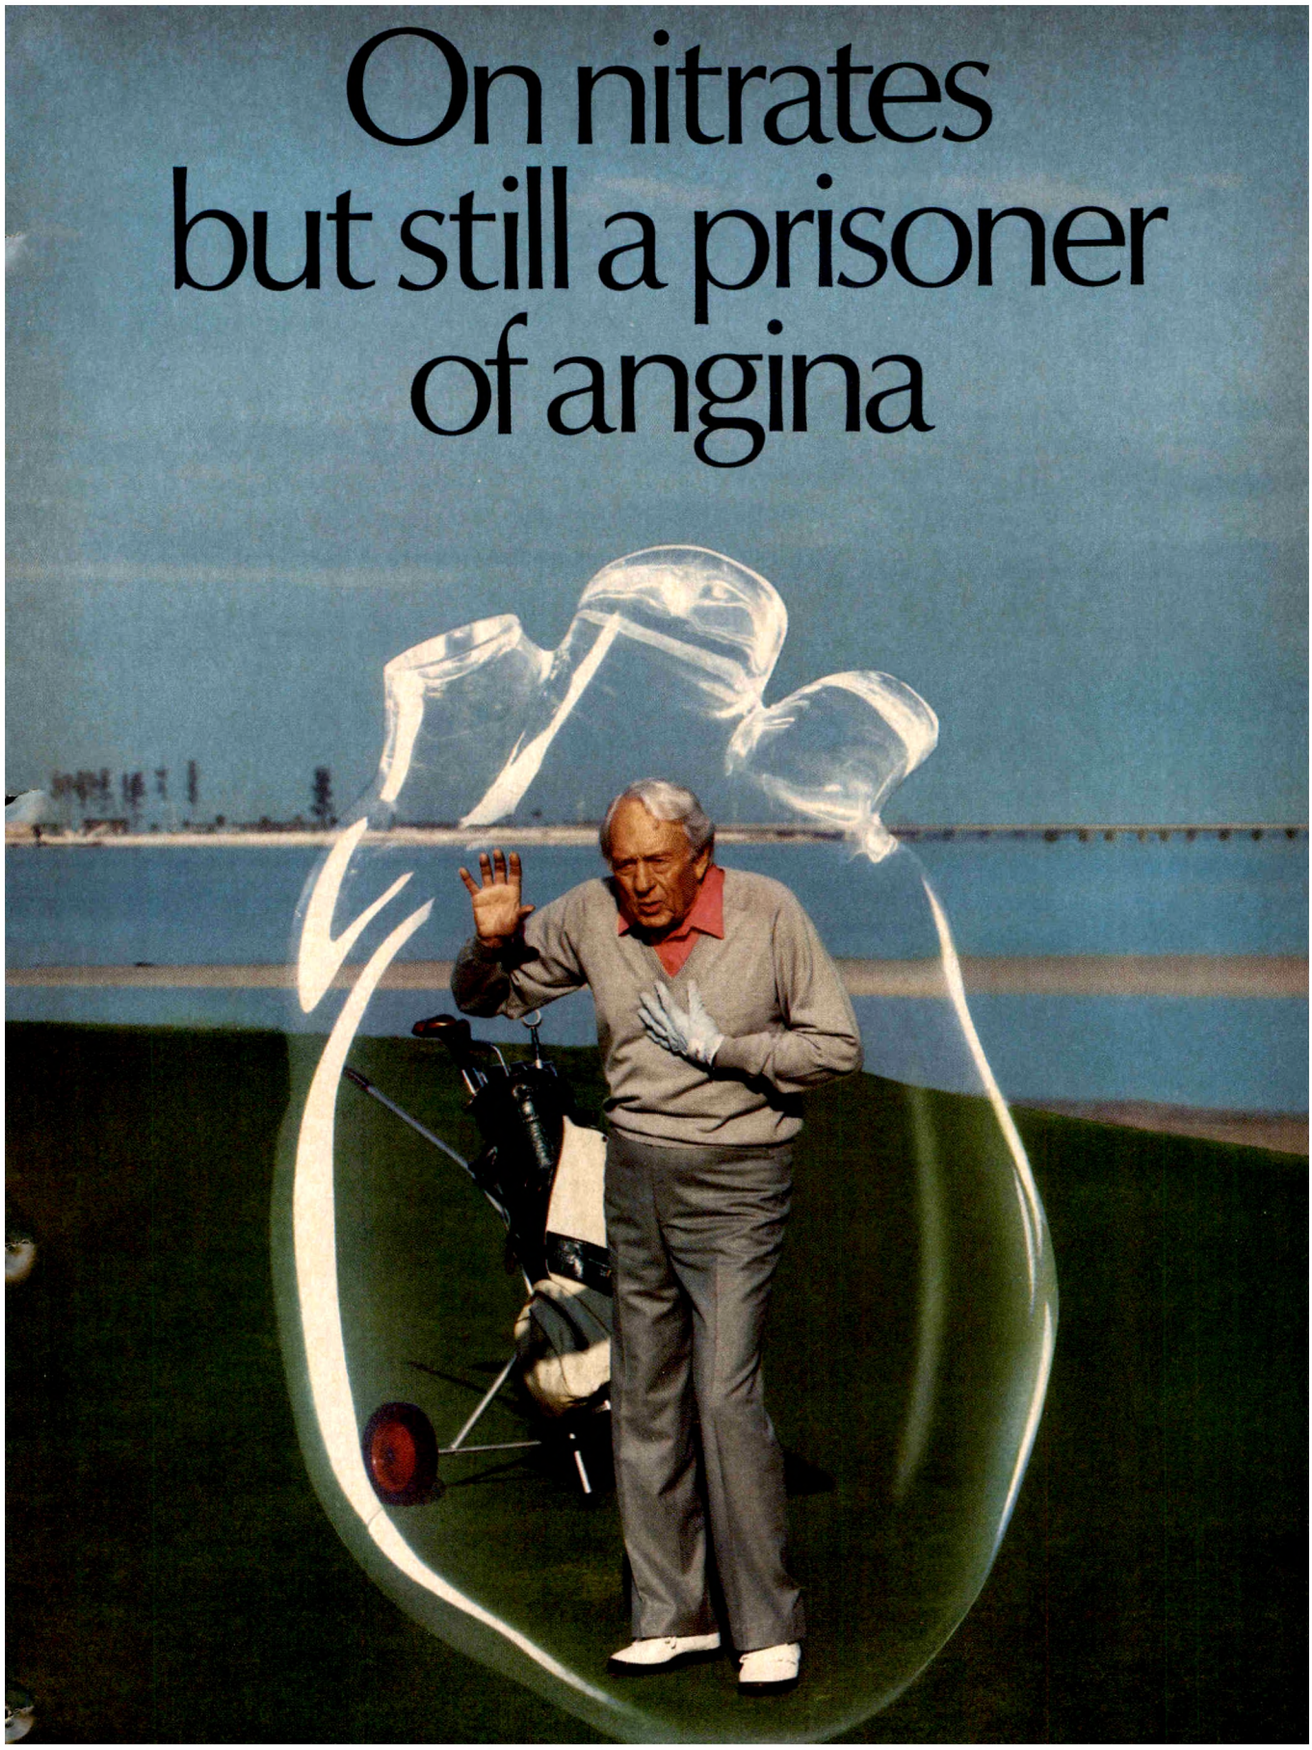
INSTRUCTIONS TO AUTHORS on page 882



On nitrates
but still a prisoner
of angina

When nitrates alone are not enough

Add Calan® TABLETS 80 mg and 120 mg (verapamil HCl)

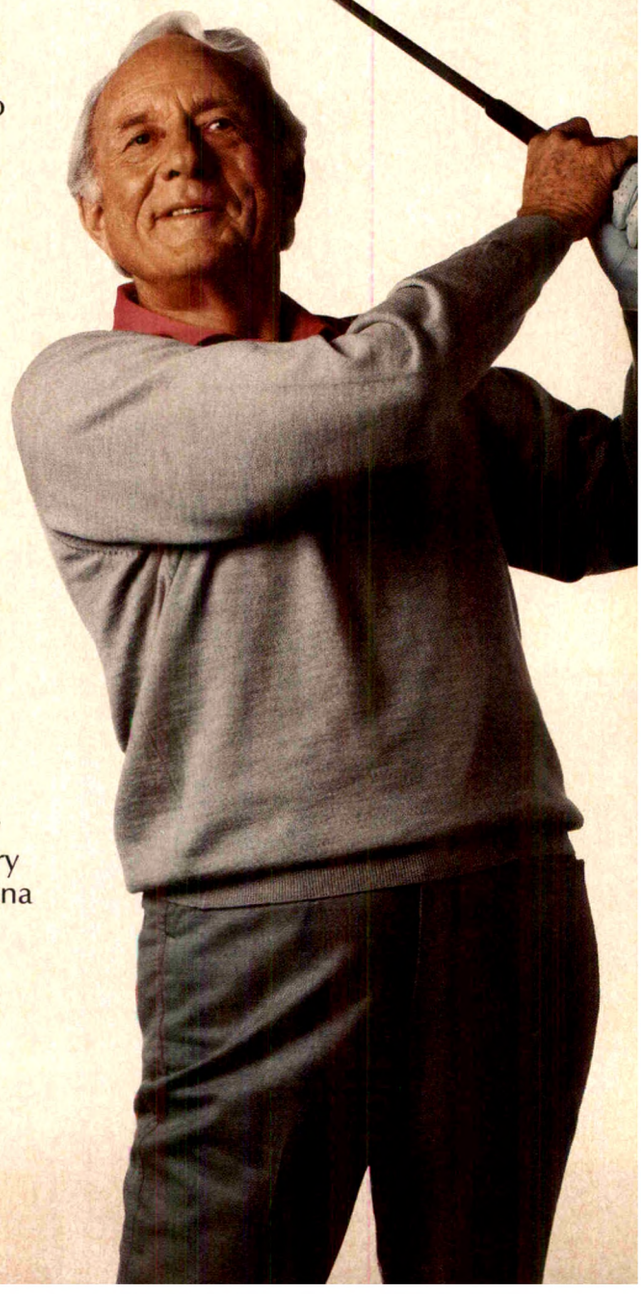
Calan plus nitrates: Unique hemodynamic benefits

- increased myocardial oxygen supply—prevents vasoconstriction both in large coronary arteries and in coronary arterioles
- reduced myocardial oxygen demand due to
  - —a reduction in peripheral vascular resistance (afterload)
  - —a decrease in venous return (preload)
  - —a modest decrease in contractility

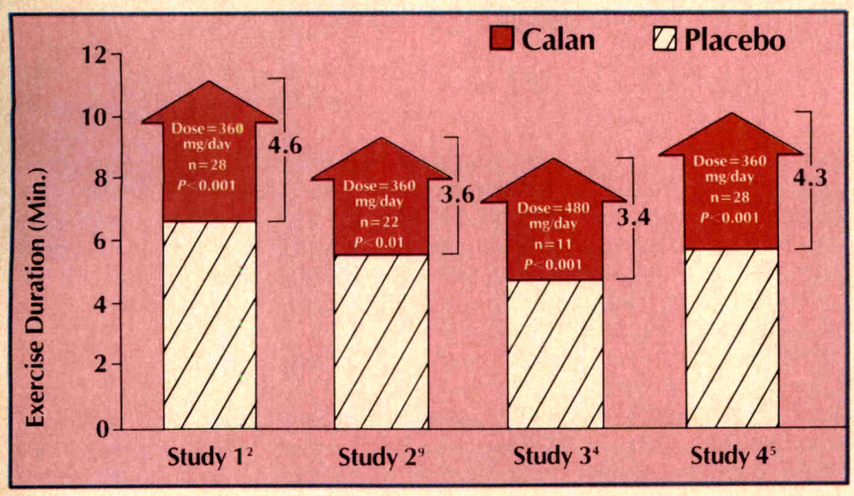
"It makes sense to treat those patients [with chronic stable angina]... [with] an agent that has a beneficial effect on both oxygen demand and supply, rather than a beta blocker which attacks just one side of that ratio."[1]

Calan plus nitrates: Efficacy for all types of angina

"...a combination of rate-lowering vasodilator (verapamil...) and long-acting nitrates...is very efficacious in patients with variant angina, angina of effort, and unstable angina at rest."[1]

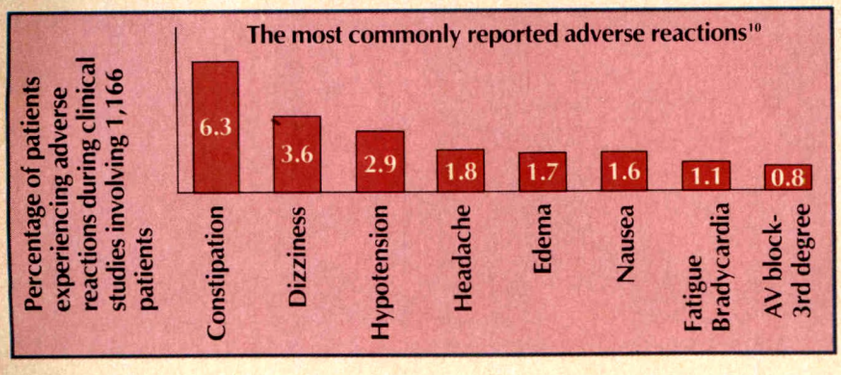


Calan efficacy: Significant improvement in exercise tolerance[2-9]



- clinically significant improvement in exercise tolerance
- clinically significant reduction in the number of attacks and the need for sublingual nitroglycerin

Calan safety: Favorable side-effects profile



With Calan, side effects such as fatigue, mental depression, impotence or bradycardia (heart rate less than 50 beats/min) seldom occur.

In one study involving 63 patients "verapamil therapy was not discontinued in any patient because of the development of adverse reactions."[8]

Calan® *TABLETS*
80 mg and 120 mg
(verapamil HCl)

SEARLE

Please see following page for a brief summary of the complete prescribing information.

5W001T

Calan® **TABLETS**
80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block.

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension, usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Elevations of liver enzymes have been reported. Four cases have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually DC-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use.

Adverse Reactions: Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, spotty menstruation, ecchymosis, bruising, gynecomastia, and psychotic symptoms. Overall continuation rate was 94.5% in 1,166 patients.

CORONARY HEART DISEASE

Prediction of Functional Capacity and Use of Exercise Testing for Predicting Risk After Acute Myocardial Infarction

ERLING BIRK MADSEN, MD, PhD, ELIZABETH GILPIN, MS, STAFFAN AHNVE, MD, HARTMUT HENNING, MD, and JOHN ROSS, Jr., MD

This study evaluated whether an ischemic exercise test response or functional capacity could be predicted from data available during hospitalization in patients discharged after acute myocardial infarction (AMI). The value of exercise test variables for predicting death and new AMI within 1 year was also examined. Among 1,469 patients, 466 (32%) underwent treadmill exercise testing around the time of discharge. An ischemic exercise test response (ST-segment depression or angina) could not be predicted. Good functional capacity (more than 4 METs) could be predicted from age and ST-segment changes at rest. Among the 60% of the patients who were predicted to have functional capacity of more than 4 METs, only 15% had poor functional capacity at the time of testing. Multivariate analysis for predicting death and new infarction selected only functional capacity (continuous variable in METs), which classified 72% of the patients into a low-risk group with less than a 2% rate of death and new AMI in the first year. The high-risk group (29% of the patients) had an 18% rate of death or new AMI. It is concluded that functional capacity is the most important exercise test variable and that patients likely to have good functional capacity can be identified on the basis of age and ST-segment changes at rest. Further, the level of functional capacity on exercise testing can identify groups of patients with very low and relatively high risk of death or new AMI within 1 year.

(Am J Cardiol 1985;56:839–845)

Exercise testing soon after acute myocardial infarction (AMI) has important prognostic implications.[1] Several exercise test variables, including functional capacity,[2–8] ST-segment depression,[3,9–18] exercise induced-angina pectoris[3,12–14,17,19,20] and ventricular premature complexes[2,5,13,19,21,22] are well established as unvariate prognostic factors. The relation between clinical variables available during the hospitalization and exercise test variables has been evaluated in only a few studies.[5,16,23] If prediction of the exercise test response based on clinical data were possible, then the value of the exercise test would decrease. Prediction of death after AMI has been made with similar accuracy using either clinical data alone, exercise test data alone or a combination of the 2 sets of data.[24]

Patients who undergo exercise testing generally have a low risk of death and new AMI, ranging from 4% to 10% during long-term follow-up.[6,13,15,17,18] Identification

Death/new AMI	155	128	(15)	27	(7)	0.0005

The mean ± standard deviation is listed for continuous variables.
AMI = acute myocardial infarction; BP = blood pressure; BUN = blood urea nitrogen; CK = creatine kinase; CT = cardiothoracic; LVEF = left ventricular ejection fraction; VT = ventricular tachycardia.

of subgroups of patients with even lower risk or relatively high risk among patients who undergo exercise testing could have important clinical applications with regard to therapy and follow-up. This study aims to clarify the following questions about the exercise test after AMI: Can an ischemic exercise test response and level of functional capacity be predicted from historical and clinical data available during the hospitalization? Can subgroups of patients who are at very low or relatively high risk of death or new AMI be identified by use of exercise test variables?

Methods

Patients: The study population consisted of 1,469 patients discharged after definite AMI. Among these patients, 466 (32%) underwent treadmill exercise testing around the time of hospital discharge (average discharge day 12 ± 4), but not later than 6 weeks after discharge. The exercise test was performed during the late hospitalization in 80% of the patients and within 2 weeks after discharge in 9%.

The patients were admitted within 24 hours after onset of symptoms to the University of California Medical Center, San Diego (55 patients), San Diego Veterans Administration Hospital (48 patients), U.S. Naval Regional Medical Center in San Diego (197 patients), and Vancouver General Hospital, Vancouver, British Columbia, Canada (166 patients), from January 1, 1979 to November 1, 1984. The data, including exercise test variables, were gathered prospectively on special forms for a data base supported by the Specialized Center of Research (SCOR) on Ischemic Heart Disease at the University of California Medical Center, San Diego. One objective of our SCOR program was to evaluate the prognostic value of various exercise test variables.

The diagnosis of AMI was established by at least 2 of the following criteria: characteristic chest pain; electrocardiographic changes with evolution of Q waves (transmural infarction); and elevated creatine kinase levels. Nontransmural infarction was diagnosed by typical ST-segment and T-wave changes accompanied by elevated creatine kinase levels.

Clinical variables: As previously described in detail,[25] clinical variables included data from the history, physical examination during the hospitalization and at discharge (e.g., maximal heart rate and pulmonary rales), laboratory findings (e.g., enzyme levels), radiographic variables (pulmonary venous congestion and cardiothoracic ratio) and the electrocardiogram (e.g., arrhythmias and ST-segment depression or elevation of at least 0.1 mV at rest). Administration of medications at the time of discharge was also noted.

In a subgroup of 750 patients, of whom 374 also underwent exercise testing, left ventricular ejection fraction (LVEF) was measured either by radionuclide techniques just before discharge or by cardiac catheterization up to 6 weeks after discharge. In another subgroup of 828 patients, of whom 280 underwent exercise testing, the presence of complex ventricular arrhythmias from a 24-hour ambulatory monitoring just before discharge was determined as previously described.[25]

Exercise testing: The exercise test was an optional part of our SCOR study protocol. In general, patients were selected for the exercise test based on the judgment of the attending physician. During the study period, exercise testing early after acute myocardial infarction became more accepted as a safe and useful test. The main reasons for not performing an exercise test were advanced age, poor general condition, severe cardiac dysfunction or disease of other organs precluding adequate exercise.

The 466 patients who underwent exercise testing had a lower frequency of clinical risk factors than patients who did not undergo exercise testing (Table I). Fewer patients who

TABLE II Variables of Univariate Importance for Ischemic Exercise Test Response (Exercise-Induced ST-Segment Depression and Angina)

		Exercise Test Response

The mean ± standard deviation is listed for continuous variables.

underwent exercise testing had previous heart failure or angina, showed signs of heart failure during the hospitalization or were treated with digitalis. The number of deaths and new infarctions within 1 year was significantly higher among the patients without exercise tests (15%) than in patients with exercise tests (7%).

Exercise test protocol: The exercise test was performed with a standard Bruce protocol[26] in 80 patients (17%), modified Bruce (Sheffield) protocol[27] in 230 (49%) and modified Balke protocol[28] in 36 (8%); in 120 (26%) further modified protocols were selected by the attending physician.

The limiting conditions for the exercise test were angina pectoris in 72 patients (16%), pronounced ST-segment changes (at least 0.2 mV depression or elevation) in 34 (7%), fatigue in 207 (44%), shortness of breath in 81 (17%), claudication in 20 (4%) and severe dysrhythmias in 9 (2%). More than 1 limiting condition was noted in some patients.

If no symptoms developed, the patients continued to exercise in most cases until they approached 75% of maximal age-adjusted heart rate. Tests in 43 patients (9%) without limiting symptoms, where the exercise test was stopped at a low heart rate, were considered indeterminate. Patients taking β-blocking agents were included if a heart rate greater than 100 beats/min was achieved at the termination of exercise, provided a functional capacity above 6 METs (1 MET = 3.5 ml O_2/kg-min) was also attained. These threshold levels were selected empirically in order to exclude patients with low work loads owing to treatment with β-blocking agents.

Medications were continued during the test, with 121 (26%) receiving digitalis, 53 (11%) procainamide and 248 (53%) β-blocking agents. ST-segment changes in patients with bundle branch block or left ventricular hypertrophy, or those receiving digitalis therapy, were considered indeterminate.

Ninety-two patients had indeterminate test results; these results were not analyzed, and 374 patients were left for further study. Among these patients, 295 had been followed for 1 year at the time of this study, of whom 19 died or had new AMIs or both.

Exercise test variables: (1) Cardiac-based reasons for stopping exercise: angina pectoris, pronounced ST-segment changes, or severe dysrhythmias. (2) Presence of typical angina pectoris during the test. (3) Functional capacity in METs, as calculated from the predicted oxgyen consumption in the protocols.[29] Functional capacity was treated both as a continuous variable and a discrete variable with a breakpoint value of 4 METs or less, which was determined to be the best breakpoint for patients who died or had a new AMI, or both, compared with patients without these endpoints. (4) Maximal heart rate at peak exercise work load. (5) Abnormal systolic blood pressure response: decrease or increase of less than 20 mm Hg during maximal exercise. (6) Exercise-induced ST-segment depression: flat or downsloping type of at least 0.1 mV compared with the ECG at rest measured 80 ms after the J point in anterior, lateral or inferior leads. If ST-segment depression at rest was present, further ST-segment depression of at least 0.1 mV was considered as exercise-induced ST-segment depression. (7) Exercise-induced ST-segment elevation: J-point elevation of at least 0.1 mV compared with the ECG at rest, without ST-segment depression in other leads. The ST-segment elevations were required to be in leads other than those exhibiting Q waves. (8) Dysrhythmias: the presence of frequent premature ventricular complexes (more than 6 beats/min), ventricular tachycardia (more than 3 consecutive ventricular complexes) or supraventricular tachycardia (more than 3 consecutive supraventricular premature complexes). (9) Ischemic exercise test response: presence of exercise-induced ST-segment depression as defined above and/or presence of angina pectoris during the test.

Follow-up: Patients were followed up by telephone interview in the year after admission. Information concerning deaths and new AMI was obtained from the death certificate or hospital records in most cases.

Statistics: The Student *t* test was used to compare mean values and a chi-square test to compare incidences of discrete variables between groups. Stepwise linear discriminant function analysis as previously described in detail[30] was performed to evaluate the independent importance of clinical variables for predicting ischemic exercise test responses or a low functional capacity and to evaluate the independent importance of exercise test variables for the prognosis of cardiac death or new AMI within 1 year. The prediction results are based on the jackknife procedure.[31] The results are presented as the percentage of correctly classified patients with the predicted endpoint, percentage of correctly classified patients without an endpoint and the percentage of the total number of patients correctly classified. In addition, the number of patients in the groups predicted either to have or not to have an endpoint was noted and the incidence of endpoints in both groups calculated to give the rates of false-positive and false-negative predictions.

Results

Prediction of ischemic exercise test response: In the 374 patients with exercise tests satisfactory for analysis, only a few clinical variables were related uni-

TABLE III Prediction of Ischemic Exercise Test Response by Discriminant Analysis of Historical Variables and Variables Available During Hospitalization

Variable	Rank	F Value
Previous angina	1	10.1
ST-segment depression at rest	2	7.2
Discharge β-blocking agents	3	6.6
Age	4	7.2
Correct classification	n	%
Ischemic exercise test response	200	58
Normal exercise test response	165	66
Total	365	61
Predicted group with ischemic test	173	47
Ischemic tests in group	116	67
Predicted group with normal test	192	53
Ischemic tests in group	84	44

variately to an ischemic exercise test response, defined as exercise-induced ST-segment depression or angina pectoris or both (Table II). The presence of ST-segment depression on the ECG at rest, indicating evidence of ischemia at rest, was important for predicting an ischemic exercise test response.

LVEF in patients with an ischemic exercise test response (mean 0.50) was not significantly different from that in patients without ischemic exercise responses (mean 0.52). Complex ventricular arrhythmias recorded on 24-hour ambulatory monitoring before discharge was the same in the 2 groups of patients (39%).

When the important variables were included in a discriminant analysis with the occurrence of an ischemic exercise test response as the endpoint, only 4 variables were selected, with the presence of previous angina ranked first (Table III). However, correct classification of patients with and without an ischemic exercise test was 61%, and the rate of false-positive responses (patients with normal tests in the group predicted to have ischemic tests) was 33% and the rate of false-negative responses (patients with ischemic tests in the group predicted to have normal tests) was also high—44%.

Prediction of functional capacity: More clinical variables were important univariately for predicting a low functional capacity (4 METs or less) (Table IV). The presence of ST-segment changes at rest (depression or elevation) was related to a low functional capacity. Also, 66% of patients with poor functional capacity had an ischemic exercise test response, compared to 47% of patients with good functional capacity. As expected, patients with low functional capacity had significantly lower LVEFs. The occurrence of complex ventricular arrhythmias on 24-hour ambulatory monitoring in patients with poor functional capacity (42%) was not significantly different from that in patients with good functional capacity (39%).

In a multivariate discriminant analysis of predictors of poor functional capacity, only age and ST-segment changes at rest were selected (Table V). The overall correct classification of patients with poor functional capacity and with good functional capacity was 68%. A good functional capacity was predicted in 60% of the patients, and among these patients only 15% had a poor test functional capacity.

Exercise test data and prognosis: In the 295 patients followed 1 year with satisfactory exercise tests, among exercise test variables tested univariately, only functional capacity in METs and the occurrence of exercise-induced ST-segment depression were important for death and/or new AMI within 1 year (Table VI).

A discriminant analysis using all exercise test variables selected only the functional capacity in METs (Table VII). Total correct classification was 75%. In the low-risk group of patients (72% of patients, functional capacity greater than 4 METs), fewer than 2% died or had a new AMI within 1 year. In the high-risk group of patients (29% of patients, functional capacity ≤4 METs), 18% reached an endpoint.

Discussion

Selection for exercise testing: Patients selected for exercise testing usually have a more favorable prognosis

Abbreviations as in Table I.

than patients who are not subjected to exercise testing.[6,18,24] Among our patients who underwent exercise testing, 7% died or had a new AMI within 1 year, compared with 15% among patients who did not undergo exercise testing.

The patients who underwent exercise testing (32%) were comparable to other populations[5,8,13,15,16] with regard to the incidence of basic clinical characteristics (Table I). However, as in other studies, the occurrence of clinical variables among the patients who underwent exercise testing is influenced by the selection criteria. Among our patients who underwent exercise testing, 56% had basilar rales during the hospitalization, which is in agreement with 48% of the patients showing signs of heart failure in another study.[5] At the time of exercise testing, 26% of our patients were treated with digitalis, compared with previously reported rates of 26%[15] and 48%.[5]

The incidence of death and/or new AMI within 1 year among the patients who underwent exercise testing (7%) was comparable to that in some previous studies (7%,[6] 8%[3]), but lower than that in other studies (10%[5,13,15] and 13%[8]) in which a greater proportion of patients were selected for exercise testing.

Exercise test protocol: The treadmill exercise tests in this study were performed with different protocols as selected by the attending physicians at each hospital. Only 17% were high-level protocols (Bruce), which may overestimate oxygen consumption. Different protocols should not be expected to influence the results, because most of the patients had limiting symptoms. Most other studies have used heart rate–limited tests, but the symptom-limited test is superior for detecting ischemic abnormalities after myocardial infarction.[32] The most frequent reason for stopping exercise was fatigue (in 44%); 16% stopped because of angina, an incidence similar to that reported in previous studies.[6,17]

TABLE V Prediction of Functional Capacity by Discriminant Analysis of Historical Factors and Variables Available During Hospitalization

Variable	Rank	F value
Age	1	41.3
Rest ST-segment change	2	13.9
Correct classification	n	%
Low functional capacity (≤4 METs)	100	66
Normal functional capacity (>4 METs)	274	69
Total	374	68
Predicted group with low capacity	150	40
Patients with low capacity in group	66	44
Predicted group with good capacity	224	60
Patients with low capacity in group	34	15

Ischemic exercise test response: The importance of previous angina pectoris[5] and ST-segment depression at rest[5] for predicting an ischemic exercise test response was confirmed in this study. The occurrence of an ischemic exercise test response could be underestimated, because some patients in this study may not have achieved a sufficient workload to detect ischemia.

In our group of 374 patients who underwent exercise testing and in whom LVEF was measured, we could not confirm the relation between a low LVEF and ischemic test response as previously reported in studies including data from 28[23] and 40[16] patients. The mean LVEF was 0.48 in our patients, compared with 0.44[16] and 0.53[23] in the 2 previous studies. The difference in findings may be explained by small groups of patients in the 2 previous reports.[16,23]

TABLE VII Prediction of Death and New Infarction One Year After Admission with Functional Capacity from Discriminant Analysis

Variables	Rank	F Value
METs	1	13.0
Correct classification	n	%
Death/new infarction	19	79
Survival/no new infarction	276	75
Total	295	75
Patients in low-risk group	211	72
Death/new infarction	4	2
Patients in high-risk group	84	29
Death/new infarction	15	18

Multivariate analysis of clinical variables has not been used before with exercise test parameters as endpoints. We found that an ischemic or normal exercise test response cannot be reliably predicted from historical or clinical variables available during the hospitalization.

Functional capacity: The importance of age for predicting functional capacity is not surprising because it is inversely related to age. The mean age of patients with poor functional capacity was significantly higher than that of patients with good functional capacity. In addition, patients with poor functional capacity also had a higher frequency of risk factors and signs of heart failure as previously reported.[5] Therefore, poor functional capacity reflects more advanced heart disease in older patients.

Use of the 2 most important variables selected by multivariate analysis (age and ST-segment changes at rest) indicated that reliable prediction of good functional capacity was possible with only a 15% rate of false-negative results (Table V). We could not predict poor functional capacity because the rate of false-positive responses was 56%. However, prediction of functional capacity overall was more reliable than prediction of an ischemic exercise response.

As an endpoint, functional capacity was dichotomized using a breakpoint value of 4 METs, which corresponded to the best discrimination between patients who did or did not die or have a new AMI. However, the relation between this breakpoint and the clinical status of the patient could be limited because some patients with a functional capacity higher than 4 METs also have clinical signs of heart failure.

Beta-blocking agents: Treatment with β-blocking agents was more frequent among patients who underwent exercise testing compared with those who did not (53% vs 38%). This finding suggests that patients treated with β-blocking agents were younger and in better clinical condition without signs of heart failure at the time of discharge, making them more suitable for exercise testing. Among patients who underwent exercise testing, more with an ischemic exercise test response were treated with β-blocking agents than patients without an ischemic exercise test response (60% vs 47%). This can be explained by a greater frequency of previous angina pectoris in patients with β-blocking drugs (31%) compared with patients not so treated (20%) ($p < 0.02$). If β-blocking agents were more frequently prescribed for patients with angina, it would not be surprising if these patients experienced more angina during testing.

Prognostic exercise test variables: Our results confirm the importance of functional capacity as the most important exercise test variable, as previously reported.[2–8] Survivors without a new AMI within 1 year achieved a significantly higher functional capacity (mean 6.2 vs 4.1 METs). Functional capacity was the only variable selected in multivariate analysis of exercise test variables.

ST-segment depression was univariately important, as reported previously,[3,9–18] but this variable was not selected by the multivariate analysis. Other exercise test variables, particularly functional capacity, are related to ST-segment depression,[6] and when functional capacity is selected first in the multivariate analysis the independent importance of ST-segment depression decreases. The same finding has been confirmed by another recent multivariate study.[8]

The definition of exercise-induced ST-segment depression could influence the prognostic value of this variable. Our definition (flat or downsloping depression of at least 0.1 mV) was in accordance with that in previous studies.[3,5,13–15] We have previously shown that quantitation of the degree of ST-segment depression did not improve its prognostic value.[6]

Prediction of death and new infarction: Use of functional capacity could identify a fairly large low-risk group of patients (72%) with a low rate of death or new AMI (2%) and a smaller group of patients (28%) with a relatively high risk (18%).

Functional capacity in patients subjected to exercise is a good predictor of the outcome 1 year after AMI. The number of prognostic endpoints in this study (19 deaths or new AMIs) precludes further analysis of the high risk group. Additional studies are needed to evaluate whether further prognostic stratification of the high-risk group is possible.

Conclusions: An ischemic exercise test response (ST-segment depression or angina pectoris) cannot be reliably predicted from historical or clinical variables from the hospitalization. Patients likely to have good functional capacity can be identified by using age and ST-segment changes at rest. Good functional capacity is the most important exercise test variable for identifying a low-risk group with very low risk of death and new AMI within 1 year. A group of patients at relatively high risk can be identified by a poor exercise test functional capacity.

Repeated Quantitative Angiograms in Coronary Arterial Aneurysm in Kawasaki Disease

HIROYUKI NAKANO, MD, KEN UEDA, MD, AKIHIRO SAITO, MD, and KEIKO NOJIMA, MD

Accurate evaluation of the extent of coronary artery lesions complicating Kawasaki disease is clinically important in patient management. Based on a total of 188 coronary angiograms and retrospective follow-up observations, the condition of coronary aneurysms was quantitatively graded as: 0 (normal)—no significant enlargement in any portion of the coronary artery; I (mild)—aneurysmal dilatation of the coronary artery evident but localized, with a maximal diameter of less than 4.0 mm; II (moderate)—maximal diameter of coronary aneurysms between 4.0 and 8.0 mm, regardless of body size; III (severe)—giant aneurysms, with the maximal diameter greater than 8.0 mm. Most mild coronary aneurysms regressed to normal within a short time, and the patient's prognosis was good. The course of grade II aneurysms varied, depending on initial angiographic coronary diameter, but all were eventually reduced in coronary size. In contrast, grade III aneurysms usually progressed to become obstructive or stenotic coronary lesions, or the large aneurysm persisted. Follow-up observations revealed that the course of coronary artery disease depended on the size and distribution of aneurysms at initial angiography. This grading of the severity of coronary lesions may provide useful criteria for predicting the prognosis of patients with Kawasaki disease. (Am J Cardiol 1985;56:846–851)

Kawasaki disease, an acute febrile illness that affects predominantly infants and young children,[1] produces coronary aneurysms during the acute stage of the illness.[2] Sudden death may result from myocardial infarction owing to thrombotic occlusion of the coronary artery.[3,4] More than half of the coronary aneurysms can regress within 1 year after onset, but some may progress into completely obstructive or markedly stenotic coronary lesions.[5] Because the morbidity and mortality of Kawasaki disease mostly depends on the extent of associated coronary artery disease, it is particularly important to assess accurately the condition of coronary lesions and to observe carefully their natural course. In the present study, we classified the severity of coronary aneurysms caused by Kawasaki disease based on quantitative coronary cineangiograms and on the retrospective study of follow-up observations. According to this classification, the outcome of coronary artery disease and factors that affect the natural course were also studied.

Methods

Patients: The present study consists of 138 patients with Kawasaki disease who underwent coronary angiography between January 1980 and December 1984 for the evaluation of coronary artery involvement. There were 80 boys and 58 girls, aged 3 months to 12 years (mean 2 years, 10 months) at the time of angiography. The interval from angiographic examination and disease onset ranged from 24 days to 9 years, and 106 patients (76.8%) underwent initial angiography within 3 months of onset. Sixty patients were found to have no cardiovascular complications at the first angiographic study, and of the remainder, 50 patients, including 38 with right and 48 with left coronary lesions, underwent repeat angiography for follow-up evaluation between 3 and 22 months (mean 11) after the initial study. Thus, 188 angiographic studies were evaluated in the current investigation. All patients who underwent repeat angiography had been receiving an antiplatelet agent, ticlopidine, 5.0 mg/kg per day, since the convalescent stage of the illness.

Protocol: The patients gave informed consent after the procedure was explained. Each patient underwent right and left coronary cineangiography in the anteroposterior projection at 60 frames/s after 0.3 to 0.5 ml/kg of metrizamide was hand injected into each coronary artery. The projected image of the end-diastolic frame was accurately traced, and thereby coronary artery size was measured. In patients without coronary lesions, the diameter was measured at the proximal segment of the right coronary artery close to the aorta and at the midportion of the left main coronary artery. When associated coronary aneurysms were present, the maximal diam-

eter of those perpendicular to the axis of the coronary artery was measured in the individual vessel. In addition to the measurement of coronary diameter, particular attention was paid to the progression into obstructive coronary changes in the repeat angiographic evaluation.

Coronary artery aneurysms were angiographically classified as solitary, multiple or extensive, according to the distribution and extent of lesions. The morphologic feature of aneurysms was classified into saccular, sacculofusiform or fusiform shape, based on the ratio of short and long axes of aneurysmal lesions.[6] The predominant lesion was distinguished as located in the proximal, middle or distal portion of the right coronary artery, and the left main, anterior descending or circumflex of the left coronary artery. The dominant coronary type was determined according to the criteria of the Coronary Artery Surgery Study.

Results

Normal coronary artery size in infants and children: Sixty patients had no associated coronary aneurysms, not even transient dilatation of the coronary artery during the acute stage of the illness. Coronary artery diameters of these subjects served as the normal control values (Fig. 1). A significant correlation was found between body surface area (BSA) and coronary artery size ($r = 0.81$ in the right coronary artery, $r = 0.74$ in the left coronary artery). In the right coronary artery, all measurements of the normal diameter were 2.5 mm or less in the patients with a BSA of less than 0.5 m^2. These values were 3.0 mm or less in the patients with BSA between 0.5 and 1.0 m^2, but were 3.0 mm or more with BSA of more than 1.0 m^2. Similar values were measured in the left coronary artery in all but 1 patient, with a BSA of 0.99 m^2 and a coronary diameter of 3.2 mm.

Coronary artery size and the extent and distribution of coronary artery involvement: The relation between the maximal diameter and the extent and distribution of coronary lesions was examined in 38 and 48 patients associated initially with right or left coronary aneurysms, respectively. The maximal diameter of a coronary aneurysm in the solitary lesion was usually 4.0 mm or less in both coronary arteries, whereas multiple or extensive lesions were usually 4.0 mm or more regardless of BSA (Fig. 2). As a result, these lesions

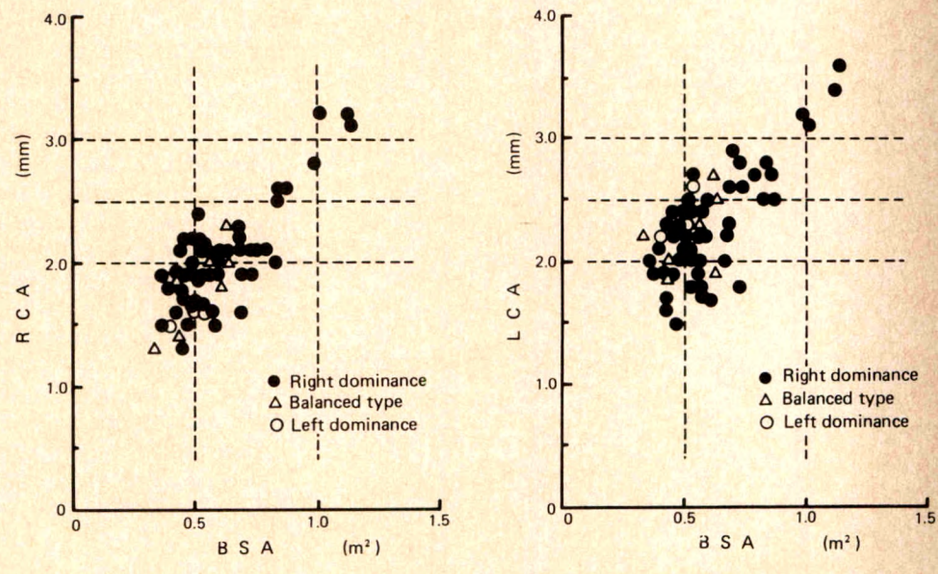

FIGURE 1. Relation between normal coronary artery diameter and body surface area (BSA). LCA = left coronary artery; RCA = right coronary artery.

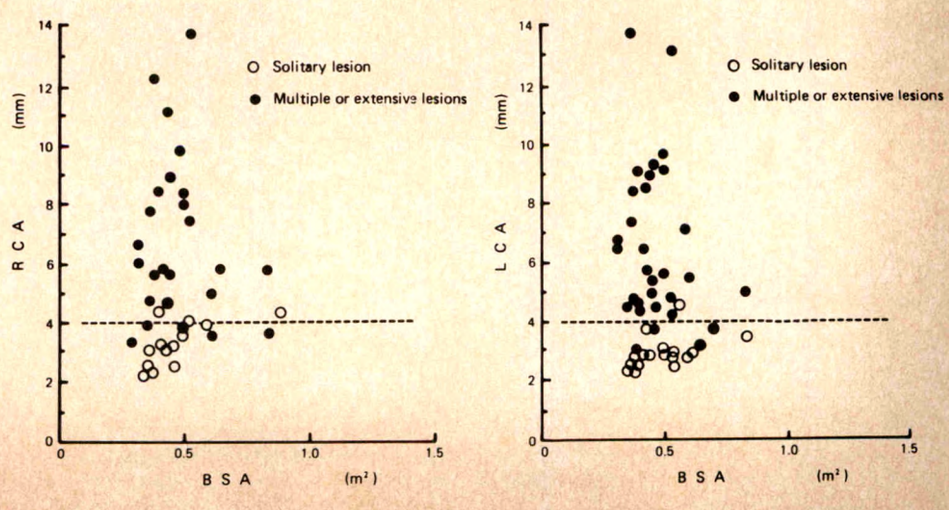

FIGURE 2. Relation between maximal diameter of coronary aneurysms and body surface area (BSA). LCA = left coronary artery; RCA = right coronary artery.

could be arbitrarily separated into groups at 4.0 mm coronary artery diameter, despite a slight overlap between the 2 groups.

Changes in coronary artery size: Coronary aneurysms of initial diameter over 4.0 mm were recognized in the right coronary artery in 25 patients and in the left coronary artery in 28 patients. Changes in size at follow-up, with or without alterations into obstructive coronary lesions, are indicated in Figures 3 and 4. In the right coronary artery, 8 patients with initial coronary aneurysms 8.4 mm or larger were proved to have obstructive coronary lesions at follow-up angiography, except for 2 patients, in whom giant aneurysms persisted almost without changes in coronary size. In contrast, all coronary aneurysms initially 7.8 mm or smaller were markedly smaller and none of the patients in this group showed obstructive coronary artery alterations at the repeat angiographic study.

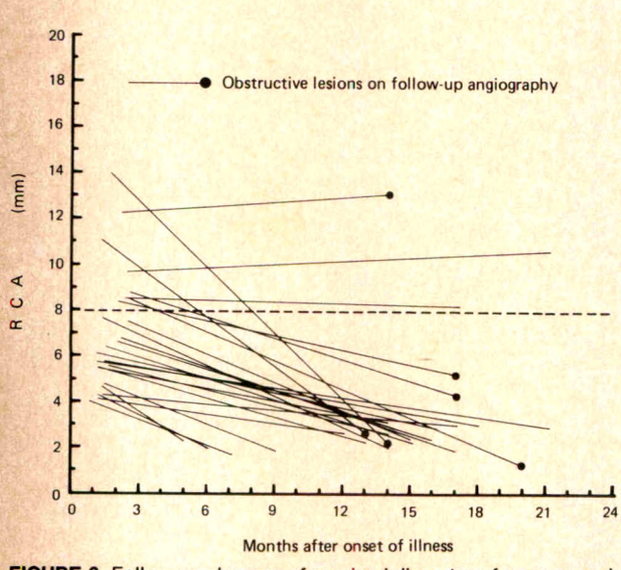

FIGURE 3. Follow-up changes of maximal diameter of aneurysms in the right coronary artery (RCA).

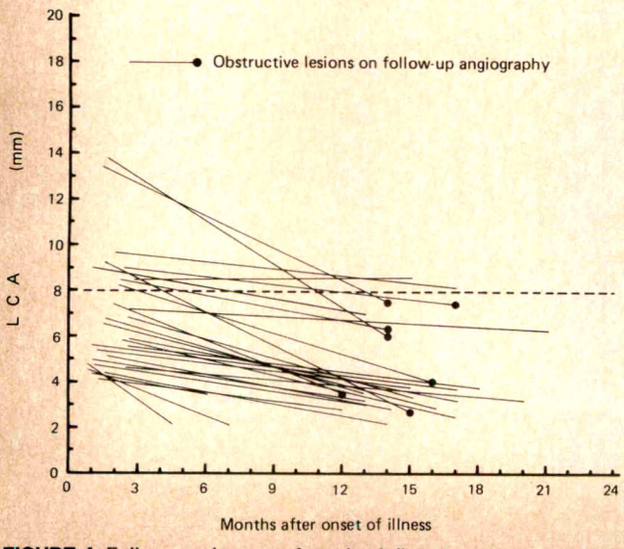

FIGURE 4. Follow-up changes of maximal diameter of aneurysms in the left coronary artery (LCA).

At the follow-up study of left coronary lesions, of 11 patients with initial aneurysms 7.2 mm or larger, coronary aneurysms changed into obstructive lesions in 7 patients and the coronary size was not significantly altered in 4. In all patients with left coronary aneurysms 6.8 mm or smaller, coronary artery diameter was substantially reduced. From these results, we set a common separation point of 8.0 mm in diameter to predict the prognosis of both right and left coronary lesions.

Classification of severity of coronary artery aneurysm: Based on the present results, the severity of coronary artery lesions caused by Kawasaki disease were graded as follows: *Grade 0* (normal)—no significant enlargement in any portion of the coronary artery. Usually the maximal diameter of the coronary artery is less than 2.5 mm in patients with a BSA of less than 0.5 m^2 and less than 3.0 mm in those of BSA between 0.5 and 1.0 m^2. *Grade I* (mild)—apparent aneurysmal dilatation of the coronary artery is evident, but localized with a diameter of less than 4.0 mm. Coronary aneurysms of mild degree are most frequently seen at the proximal segment of the right coronary artery and at the bifurcation of the left anterior descending and left circumflex coronary artery, indicating a "web" appearance (Fig. 5). *Grade II* (moderate)—the maximal diameter of coronary aneurysms between 4.0 and 8.0 mm, regardless of age and BSA. Coronary artery lesions in this group may be solitary, multiple or extensive (Fig. 6). If coronary lesions are multiple or extensive even with a maximal coronary size of less than 4.0 mm, the lesion should be classified as grade II. *Grade III* (severe)—giant aneurysms of the coronary artery with a maximal diameter greater than 8.0 mm. Generally, coronary lesions are extensive and diffuse, involving more than 1 vessel (Fig. 7).

Follow-up evaluation of coronary artery lesions: The changing outcome of right or left coronary artery lesions found shortly after the acute stage of Kawasaki disease was observed in 50 patients undergoing initial angiography within 3 months after onset of the disease (Fig. 8). Follow-up angiography was performed in selected patients when coronary aneurysms were proved

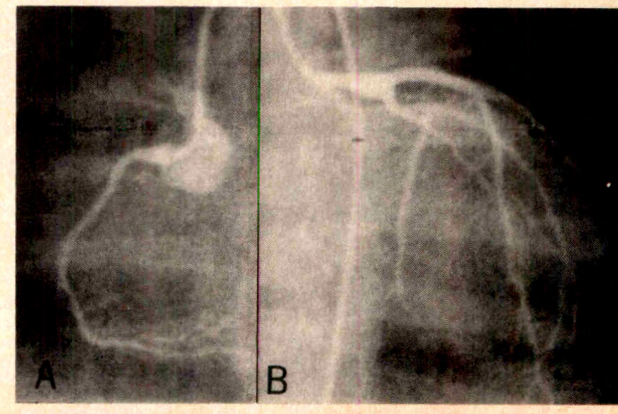

FIGURE 5. Right (**A**) and left (**B**) coronary aneurysms of mild degree (grade I) documented on coronary angiograms. Mild aneurysms are most frequently seen at the bifurcation of the left anterior descending and the left circumflex coronary arteries, giving a "web" appearance.

to have regressed to normal appearance on serial 2-dimensional echocardiography, and was performed about 1 year after initial angiography in the remaining patients. In both coronary arteries, most initial coronary lesions of grades I and II regressed to normal or improved to grade I at follow-up study, whereas almost all grade III lesions progressed to become obstructive lesions (Fig. 9) or were unchanged.

Factors influencing the course of coronary artery lesions: To investigate factors that influence the natural course of coronary artery disease, the subjects (38 with right and 48 with left coronary lesions) were separated into 2 groups. Group I included patients whose aneurysms became smaller or regressed to normal at follow-up angiography; group II included patients whose aneurysms progressed into obstructive lesions or did not change. The effects of the following factors on the outcome of coronary lesions in each group were examined: patient's age at onset of Kawasaki disease; gender; dominant coronary type; whether pulse corticosteroid therapy was performed during the acute febrile period; and the characteristics of coronary aneurysms documented at initial angiography, such as the grade of severity described herein, location, distribution and morphologic characteristics. The number of subjects in each item is listed in Table I and statistical analysis by chi-square test revealed that the grade represented by the condition of the coronary artery and the distribution of lesions in both coronary arteries were significantly related to the differences between the 2

groups. Factors other than the size and distribution of the coronary artery were shown not to contribute to the natural course of coronary artery disease.

Discussion

Coronary artery aneurysm is a serious cardiovascular complication of Kawasaki disease, which occurs in 15 to 20% of patients with the illness.[7,8] The size and distribution of coronary lesions have a broad spectrum, from transient, slight enlargement to giant aneurysms. Two-dimensional echocardiography has been used to evaluate the extent of these coronary artery lesions.[8–10] However, echocardiographic measurements of coronary artery size have some limitations,[11] with unsatisfactory results in the detection of slight coronary changes as well as obstructive and stenotic coronary lesions. Angiographic evaluation, therefore, may be required for accurate and objective assessment of coronary artery involvement of this disease.

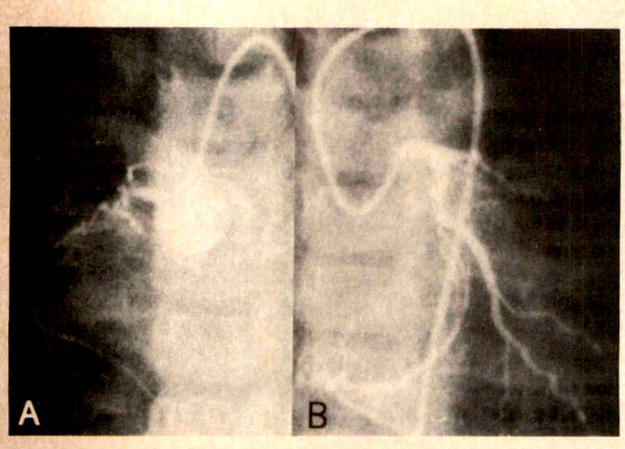

FIGURE 9. Obstructive lesions documented on coronary angiography. **A,** segmental stenotic lesions of the right coronary artery suggesting coronary recanalization. **B,** complete obstruction of the left anterior descending coronary artery.

Angiographic measurements of the normal coronary diameter in infants and children varied depending on body size and the dominant type of the coronary artery.[10] Based on the present results, we could define the upper limit of normal value for coronary artery diameter in terms of BSA. Although somewhat higher values for left coronary diameter and lower values for right coronary diameter were recognized in patients with left dominance of the coronary artery, the normal range described herein was considered applicable to almost all patients regardless of the dominant coronary type.

A close relation was found in both coronary arteries between maximal size and distribution of coronary lesions, and we can separate into 2 groups, grade I and II, as to the severity of coronary lesions at the critical size of 4.0 mm in diameter. Giant aneurysms, of the maximal

diameter of more than 8.0 mm, were associated with a serious prognosis with respect to coronary lesions. Despite administration of antiplatelet drugs, large aneurysms resulted more readily in thrombotic occlusion of the coronary artery, or even if thrombus formation was averted, these large aneurysms remained almost unchanged irreversibly. In contrast, coronary lesions of less than 8.0 mm tended to regress over time. As a result, the coronary artery size of 8.0 mm may represent the critical level to distinguish whether reversible changes of regression may develop in the course of the disease. From all the results, including follow-up observations, we have classified from grade 0 to grade III the severity of coronary artery aneurysms after Kawasaki disease, taking into consideration the size and prognosis of the coronary lesions.

The effect of treatment during follow-up may contribute to the changing outcome of coronary artery lesions. Kato et al[5,7] suggested that aspirin reduced the incidence of coronary artery thrombosis, but their observations in conjunction with the extent of coronary lesions remained obscure. In the present study an antiplatelet agent was uniformly given to all patients after the acute period of the illness, and thus the effect of treatment was unrelated. On the other hand, corticosteroid[7,12] may increase blood coagulability and has the risk of delaying the healing process of coronary arteritis, resulting in the occurrence of coronary aneurysms. However, our study indicates that this agent did not play a significant role in the natural course of coronary aneurysms already developed.

The current study also indicates that the outcome of coronary artery disease was affected only by the size and distribution of the initial coronary lesions. Morphologic characteristics and location of initial coronary aneurysms and coronary dominant type appeared not to be directly related to alterations in the lesions. The major determinant of the prognosis was the initial size of the coronary aneurysms, and therefore we can predict the course of coronary artery disease from angiographic findings shortly after onset of the illness.

Mild coronary aneurysms may return to normal within a short time. The course of moderate-sized aneurysms (grade II) varies, depending on initial size and distribution, eventually with marked reductions in coronary size in most instances. From the clinical viewpoint, the prognosis of patients with grade II aneurysms appears not to be serious, but premature atherosclerotic changes of the coronary artery should be followed carefully.[13] Giant coronary aneurysms (grade III) as well as obstructive coronary lesions were usually associated with impaired left ventricular function resulting from myocardial ischemia.[14] Furthermore, myocardial infarction exclusively occurs in association with large aneurysms or obstructive lesions following Kawasaki disease.[3,14,15] Of clinical importance is the prevention of coronary artery disease, and even if coronary aneurysms should occur, every effort should be made to preclude the development of very large aneurysms.

Identification of Best Electrocardiographic Leads for Diagnosing Myocardial Infarction by Statistical Analysis of Body Surface Potential Maps

FRED KORNREICH, MD, PhD, PENTTI M. RAUTAHARJU, MD, PhD,
JAMES WARREN, MSc, TERRENCE J. MONTAGUE, MD, and B. MILAN HORACEK, PhD

This study describes a practical approach for the extraction of diagnostic information from body surface potential maps. Body surface potential map data from 361 subjects were used to identify optimal subsets of leads and features to distinguish 184 normal subjects from 177 patients with myocardial infarction (MI). Multivariate analysis was performed on 120-lead data, using as features instantaneous voltage measurements on time-normalized QRS and STT waveforms. Several areas on the map, most of which were located outside the precordial region, contained leads with important discriminant features; 2 of the 3 limb leads (aVR and aVF) also exhibited high diagnostic capability. A total of 6 features (mostly STT measurements) from 3 locations accounted for a specificity of 95% and a sensitivity of 95%; these were the right subclavicular area, the left posterior axillary region and the left leg. As a comparison, the same number of features from the standard 12-lead electrocardiogram yielded a sensitivity of 88% for a specificity of 95%. To investigate the repeatability of the results, the entire population was separated into a training set (100 normal subjects and 100 patients with MI) and a testing set (84 normal subjects and 77 patients with MI); computing a discriminant function on the training set and applying it to the testing set only moderately deteriorated the diagnostic classification. It is concluded that this approach achieves efficient information extraction from body surface potential maps for improved diagnostic classification. (Am J Cardiol 1985;56:852–856)

Data reduction and information extraction are now the fundamental problems in the analysis of electrocardiographic body surface potential maps. Extensive arrays of electrocardiograms are being used to obtain high-quality surface maps; however, in some important applications, such as exercise testing and coronary care unit recordings of patients with acute myocardial infarction (MI), the smallest subset of leads that still contains the essential information present in the complete map may be desirable. Various subset studies have sought the subset that would provide optimal signal representation.[1–3] However, the subset of leads that optimally accounts for the signal information in body surface potential maps is not necessarily optimal for diagnostic classification. To identify the best combinations of electrocardiographic leads and their features for optimally representing diagnostic information characteristic of MI, we performed multivariate analysis of map data, consisting of 120 simultaneously recorded leads, from 184 normal persons and 177 patients with MI.

Methods

Study population: Three hundred sixty-one subjects were studied. Group A consisted of 184 normal control subjects; group B consisted of 177 patients who had had MI. Group A subjects had no evidence of heart disease by history, physical examination, 12-lead electrocardiogram and echocardiogram. They ranged in age from 20 to 50 years (mean 34). Group B patients had a typical history of cardiac chest pain and characteristic changes in enzyme levels, and in most cases the diagnosis of MI was substantiated by coronary angiography and ventriculography; this group consisted of 44 women and 133 men and included 39 patients with acute MI (less than 1 week), 30 patients with recent MI (between 1 week and 1 month) and 108 patients with old MI (more than 1 month). Patients in this group were 34 to 71 years old (mean 55). All patients with MI were grouped together because breakdown of the population according to the location of the infarct would have yielded subgroups far too small for reliable statistical analysis.

Body surface potential mapping: For each subject, we recorded simultaneously on digital tape the electrocardiographic signals from 117 torso and 3 limb electrode sites, sampling each channel 500 times per second and using the Wilson central terminal as a reference potential. The tracing quality was monitored visually during the recording. Later, the stored data were processed by performing selective averaging, and again carefully inspected and edited. Details of the

procedure have been reported.[4] We time-normalized separately the QRS waveform and ST-T waveform and represented them by 70 and 180 points, respectively.

We computed averaged 120-lead maps separately for the normal and the MI populations by averaging sample-by-sample time-normalized electrocardiograms from subjects in each group. Difference maps were then calculated by subtracting corresponding sample values of 120 averaged signals of the normal and MI groups. Although difference maps could be viewed as a means for guiding the selection of optimal leads and features for the separation of the 2 groups, they do not truly reflect the ability of measurements to discriminate, because they fail to take into account the intragroup variability. Therefore, a particular kind of difference map was designed, aiming at representing the discriminant power of each sampling point of each of 120 signals. The discriminant maps were obtained by dividing each instantaneous difference with the corresponding standard deviation computed from the pooled population. The values thus achieved, referred to as discriminant indexes, were in fact strictly proportional to corresponding Student t-test statistics and provided information on the capability for each measurement, in each lead, to separate the MI group from the normal group. Although inspecting discriminant maps may provide clues for selecting the best leads and for extracting optimal features for any bigroup or multigroup differentiation, we attempted to verify this by more rigorous statistical analysis.

Feature extraction and statistical analysis: We used instantaneous amplitude measurements obtained by sampling time-normalized QRS and ST-T waveforms at equal intervals; this resulted in 8 samples for QRS and 7 samples for STT, i.e., 15 × 120 per subject. The statistical procedure involved 2 steps that were performed by programs from the Biomedical Computer Program library (BMDP 7M).[5] First, the best classifiers were selected from the total number of available features by a stepwise selection; then these selected classifiers were combined into the properly weighted linear discriminant functions.

Because the number of variables was so large (1,800 instantaneous measurements per patient), the program processed 80 input variables at a time and selected the 20 best from each batch, repeating the procedure until it obtained a final set of 20 optimal classifiers. Varying the composition of the batches and their order of entry did not affect the first 8 classifiers selected.

Results

The 120-lead discriminant map for normal subjects and patients with MI (Fig. 1) reveals that: (1) Leads with the largest discriminant indexes (e.g., leads located

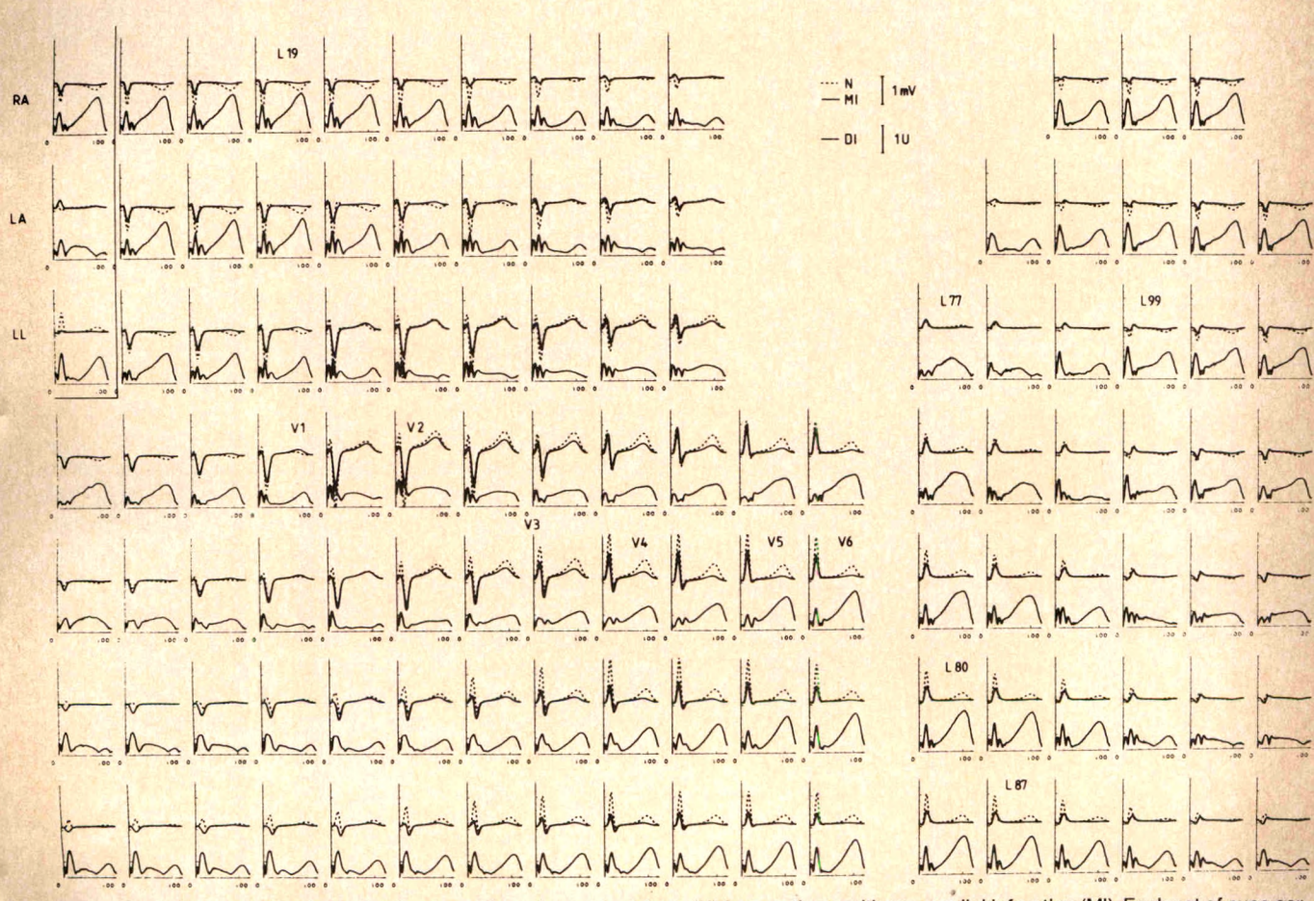

FIGURE 1. Discriminant 120-lead map for the separation of normal subjects (N) from patients with myocardial infarction (MI). Each set of axes corresponds to electrode sites; the **larger box** in the **upper left** corner contains the 3 unipolar limb leads: right arm (RA), left arm (LA), left leg (LL). The **top row** is at the level of the sternal notch and the **bottom row** at the ombilical level. A wider vertical gap separates the anterior from the posterior portion of the thorax. Electrode sites are labeled: V_1 to V_6 for the precordial leads and L 19, L 77, L 80 and L 99 (see text). Each axis set contains 3 curves: the 2 superimposed upper tracings represent averaged, time-normalized (every second point is plotted) electrocardiographic waveforms for normal subjects (**dotted line**) and patients with MI (**solid line**), respectively; the **bottom curve** depicts the absolute value of the instantaneous discriminant index as it varies in time. The amplitude of the discriminant index (DI) equals 1 unit (1U) when the corresponding mean voltages for normal subjects and patients with MI are 1 (pooled) standard deviation apart.

* Six instantaneous measurements (listed in Table I) are used.
† ½ (specificity + sensitivity).
MI = patients with myocardial infarction; N = normal subjects.

complex; in most leads the discriminant ability is restricted exclusively to QRS or STT; the "best" leads, however (e.g., leads 19 and 80), perform well in both intervals. (3) The maximal discriminant index during depolarization often coincides with the peak of QRS, which is between the 3/8 and the 4/8 QRS (e.g., left leg and lead 19), but it can also appear early in QRS as in lead 99. (4) Except for leads V_5 and V_6, the precordial leads have lower discriminatory capacity than do the limb leads.

Table I is a list of the results of the discriminant analysis. Only the first 6 variables are tabulated, because little improvement was noted beyond this point. The bulk of the separation (92% correctly classified patients) is achieved with the first 3 variables, measured on leads 80, aVF and 19, respectively. These 3 leads originate from the sites previously described as containing maximal diagnostic capability. The discriminant index for lead 77 peaks in late ST and early T, a pattern different from those in the other leads with high discriminant T indexes. Similarly, the maximal discriminant index is for lead 99 in early QRS. These discrepancies suggest the presence of independent information in these leads. The first 6 measurements selected by the stepwise procedure are shown in Figure 2 and listed in Table I.

To investigate the repeatability of the diagnostic results, we separated the available population into a training set (100 normal subjects and 100 patients with MI) and a testing set (84 normal subjects and 77 patients with MI). A new linear discriminant function was computed in order to separate the 2 groups of the training set. Running the thus calculated discriminant function on the testing set permitted the classification of the remaining patients. The results of this investigation are shown in Table II. A moderate overall deterioration of about 2% was noted.

The diagnostic performance achieved with multivariate analysis on body surface potential maps was also compared with the standard 12-lead electrocardiogram. The first 3 features, accounting for a sensitivity of 84% (specificity kept at 95%), originated from leads aVR (STT), aVF (QRS) and V_6 (STT). Also, the stepwise procedure was repeated by restricting the choice of leads to the 3 best leads previously selected (leads 80, aVF and 19). The results are shown in Table III. The difference of performance between the 2 lead sets was statistically very significant ($p < 0.001$).

Table IV shows the discrepancy between optimal signal representation and optimal diagnostic representation for lead subsets. In a separate study using the same data, we designed a stepwise procedure for se-

MI = myocardial infarction; N = normal; RMS = root-mean-square; SE = sensitivity; SP = specificity.

lecting leads that optimally predicted all the remaining ones in a least-squares, best-fit sense. After 3 steps, the total signal information accounted for reached 88.3% of the root-mean-square voltage. The selected leads were located in high-voltage areas (Fig. 3). With specificity kept at 95%, the diagnostic leads had 95% sensitivity even though they represented only 81.5% of the signal information.

Discussion

Limitations of the study: This study's main limitation is its restriction to a comparison between 2 rather clear-cut groups. Therefore, the optimal diagnostic leads arrived at are only valid for these groups. Before they can be said to have more general diagnostic use, they must be tested in new independent samples. Although other pathologic groups will probably require different lead sets, each of these sets may find its particular clinical application, such as in the coronary care unit or in the exercise electrocardiography laboratory.[6,7]

Discriminant power of body surface potential maps: The differences between averaged normal and MI maps do not necessarily indicate which leads and measurements can be considered potential discriminators. In fact, the largest absolute differences are observed near the vertical level of lead V_4 for QRS and between leads V_4 and V_5 for ST-T, but inspection of the discriminant map (Fig. 1) shows that neither area displays maximal diagnostic capabilities during QRS or ST-T. We therefore turned to discriminant maps in which each difference was scaled by the pooled standard deviation; this yielded instantaneous values (discriminant indexes), which were plotted as a function of time. Peripheral areas of the maps (including the limb leads) with the smallest unscaled differences have the largest scaled differences; this situation is reversed in the precordial leads, in which the large differences are offset by the equally large interindividual variability. Although most of the best leads (leads 19, 80 and aVF) that were found by statistical analysis were identified from the discriminant map, "good" areas (e.g., the lower anterior thoracic row at the umbilical level for QRS and the high dorsal region below the neckline for ST-T) did not contribute to the final subset, and other, seemingly

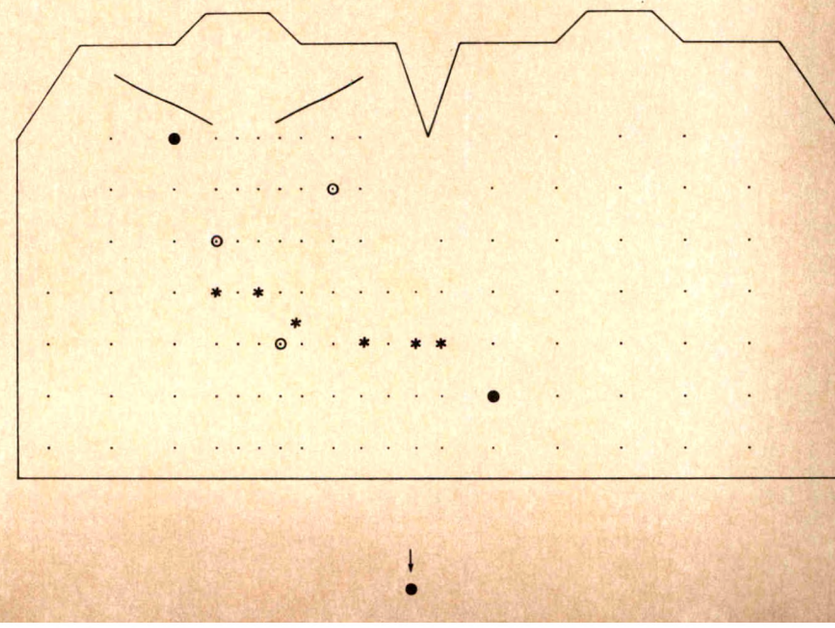

FIGURE 3. Schematic unfolded thorax. **Small dots** represent the electrode sites at which 120 electrocardiograms were simultaneously recorded, **small stars** the position of the precordial leads V_1 to V_6, **open dots** the electrode sites where electrocardiograms for maximal signal representation can be recorded and **black dots** the positions with maximal diagnostic information for the separation of normal subjects from patients with myocardial infarction.

unlikely candidates (e.g., lead 77), were selected. The essence of multivariate analysis is to reject redundancy when present and to combine variables that contribute independently to the overall classification. Therefore, all leads and all measurements must be analyzed.

Feature extraction from body surface potential maps: Although time-normalized QRS and ST-T waveforms can be considered adequate for the diagnostic sampling of electrocardiographic signals if they are represented by samples taken at 8 equal intervals,[8,9] we found that 8 QRS samples did not include some instances with maximal discriminant indexes. A separate study was conducted by adding peak QRS measurements to the already available QRS variables. No difference in the end performance was observed. As for the selected features, the bulk of the discrimination is achieved on the basis of voltage criteria (near-maximal amplitude as in 6/8 ST-T and 4/8 QRS). More subtle differences (3/8 ST-T or 2/8 QRS) show up in later steps.

Lead selection, lead subsets, and signal versus diagnostic information: The best leads originate from peripheral areas; their choice was not critical, because several leads in the same clusters showed similar abilities. Restricting the analysis to the 3 best leads did not significantly alter the diagnostic results, because most of the separation was achieved with the first 3 steps.

Finally, the discrepancy between optimal signal representation and optimal diagnostic representation for lead subsets has been illustrated earlier (Table IV, Fig. 3). In view of these results, the strategy for the selection of lead subsets will differ whether the former or the latter representation is sought. Optimal subsets for estimating total body surface potential distributions have been proposed by Barr et al[1] and later by Lux et al.[3,10] Their subsets, consisting of 24 and 32 leads, respectively, were optimal in the sense of least-mean-squared error for the representation of electrocardiographic signals at unmeasured sites.

The present study focuses mainly on selecting the smallest subset of optimal leads and features for separating normal subjects from patients with MI, irrespective of the site of the infarcts. The selected subset was arrived at on the basis of optimal diagnosis, not of optimal signal representation.

Extending the method to new groups may produce a lead set that is satisfactory for all diagnostic purposes or, more likely, different lead sets for different purposes. Lead sets that have optimal diagnostic ability may not account for, or allow, the reconstruction of the whole map, but they will preserve the map's practical information content.

Assessment of Left Ventricular Aneurysm Resectability by Two-Dimensional Echocardiography

CEES A. VISSER, MD, GERARD KAN, MD, RICHARD S. MELTZER, MD, AD C. MOULIJN, MD, GEORGE K. DAVID, MD, and AREND J. DUNNING, MD, *With the technical assistance of* MARGA van CORLER *and* HARRY de KONING

Mortality of surgical resection of a left ventricular (LV) aneurysm is largely determined by size and function of nonaneurysmal or residual myocardium. A residual myocardial index was determined using 2-dimensional echocardiography (2-D echo) in 56 consecutive patients scheduled for LV aneurysmectomy, and these results were correlated with surgical outcome. The index was calculated using 3 apical cross sections: the 2- and 4-chamber views and the long-axis view. These views were recorded at mutual angles of 60°. In each view the end-diastolic length of normally moving endocardium of the 2 opposite walls was expressed as a fraction of the end-diastolic LV long axis. The index was assessed by averaging the 6 ratios obtained. In 41 survivors the index ranged from 40 to 71% (mean ± standard deviation 53 ± 7.8) and in 15 nonsurvivors from 29 to 67% (mean 38 ± 8.5, $p < 0.01$). With 1 exception, this echocardiographic index sharply separated survivors from nonsurvivors. The lower limit to survive aneurysmectomy was 40%.

(Am J Cardiol 1985;56:857–860)

Left ventricular (LV) aneurysm is a common complication of acute myocardial infarction. The incidence of postinfarction aneurysm reportedly varies between 10 and 38%.[1–7] Resection of an LV aneurysm in symptomatic patients may lead to a significant improvement in a functional class.[8–14] However, the rest of operative mortality may be high; mortality rates as high as 50% have been reported.[15–18] Thus, appropriate patients must be selected for this procedure. Until recently little agreement existed concerning invasive predictive measurements such as cardiac output, ejection fraction and LV end-diastolic pressure.[14,19,20] More recent studies, however, have shown that the postoperative results of LV aneurysmectomy are largely determined by the size and function of the nonaneurysmal or residual myocardium.[21–23] We examined whether patients most likely to survive LV aneurysmectomy could be identified by assessing the extent of residual myocardium by 2-dimensional echocardiography (2-D echo).

Methods

The study comprised 56 consecutive patients selected to undergo resection of an LV aneurysm secondary to coronary artery disease. There were 44 men and 12 women, mean age 52 ± 18 years. Seventeen patients (30%) underwent operation within 4 weeks after infarction. Almost all patients had 2 or more symptoms, including angina pectoris, congestive heart failure or ventricular tachycardia. The predominant indication for surgery of the whole group was congestive heart failure in 39 patients, refractory ventricular tachycardia in 10 and severe angina pectoris in 7. Congestive heart failure was the main indication in 13 of 17 patients (76%) who underwent aneurysmectomy within 4 weeks after infarction, and in 26 of 39 patients (67%) who underwent operation later. An aneurysm was documented in all patients by both cineangiography and 2-D echo and was defined by both methods as a well demarcated bulge in the contour of the LV wall during both diastole and systole and dyskinesia or akinesia.[24]

Two-dimensional echo was performed with use of a wide-angle, commercial mechanical sector scanner (ATL 300 or Ekosector 10A). All patients were studied in the left lateral decubitus position, and a standard echocardiographic approach was performed in which multiple LV parasternal long- and short-axis views were obtained as well as the apical 2- and 4-chamber views and the apical long-axis view.[25] These 3 apical cross sections were applied to assess the size of the residual myocardium. To improve spatial orientation of this part of the left ventricle, we fixed a calibrated ring containing oil and an air bubble to the body of the transducer. This device guarantees a mutual angle of 60° between the 3 apical cross sections.[26] Figure 1 is a schematic diagram of how we calculated the residual myocardium of the left ventricle with an apical aneurysm. After reviewing each cross section in real-time, slow-motion and still-frame formats, the end-diastolic length of the normally moving endocardium of each of the 6 walls of the left ventricle was estimated and expressed as a fraction of the end-diastolic long-axis length of the left ventricle. A residual myocardium index was then assessed by averaging the 6 ratios obtained and multiplying this by 100%. In the schematic example in Figure 1 the index calculated was 55% (see also Fig. 2).

Images were recorded on videotape and later analyzed by 2 observers who were blinded to each other's interpretation

methods

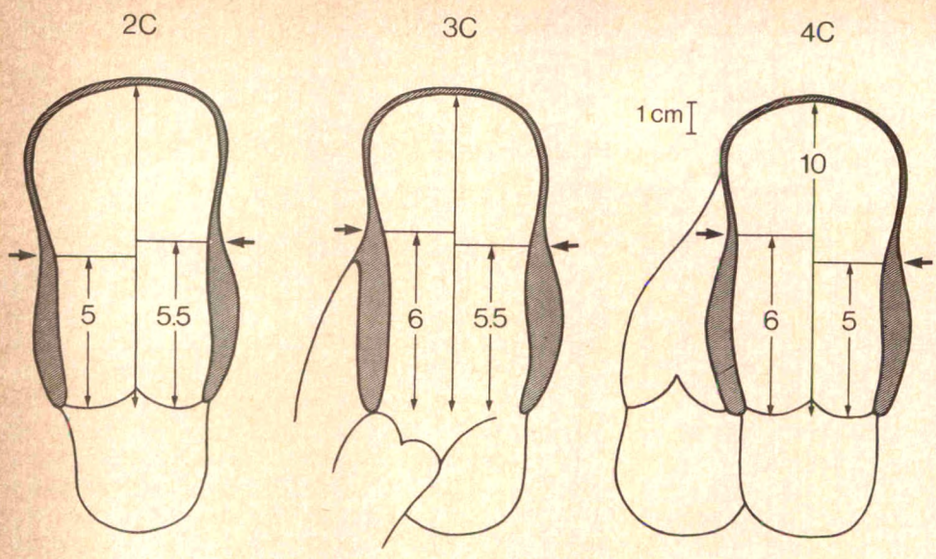

FIGURE 1. Method of evaluating the residual myocardial index of the left ventricle (RMI_{LV}). **Black arrows** indicate the separation between the normally moving endocardium and the apical aneurysm. The end-diastolic length of the normally moving endocardium of each of the 6 walls was expressed as a fraction of the end-diastolic long-axis of the left ventricle. 2C = 2-chamber view; 3C = apical long-axis or 3-chamber view; 4C = 4-chamber.

$$RMI_{LV} = \frac{\left(\frac{5}{10}+\frac{5.5}{10}\right)+\left(\frac{6}{10}+\frac{5.5}{10}\right)+\left(\frac{6}{10}+\frac{5}{10}\right)}{6} \cdot 100\% = 55\%$$

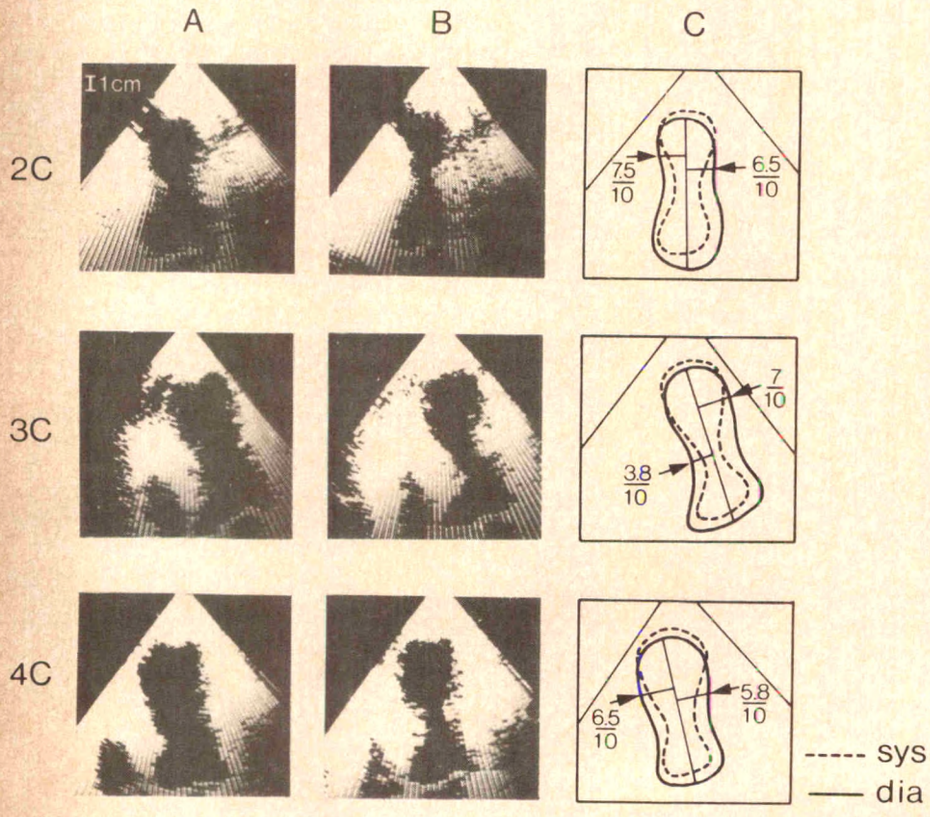

FIGURE 2. End-diastolic (**A**) and end-systolic (**B**) stop frames of a patient with an apical aneurysm. The line drawing (**C**) shows the endocardial outlines at end-systole (sys) and end-diastole (dia). The index in this patient was 61%. Other abbreviations as in Figure 1.

$$RMI_{LV} = \frac{1.4+1.08+1.23}{6} \cdot 100\% = 61\%$$

and the surgical outcome. Interobserver variation was low (r = 0.95). Disagreement was finally resolved by consensus upon repeat review of the recordings.

Results

Studies suitable for analysis were recorded in all 56 patients. The aneurysm was located at the anteroapical wall of the left ventricle in all but 1 patient, who had a circumscript but large basal aneurysm of the inferoposterior wall. The echocardiographic and cineangiographic site of aneurysm correlated closely.

Surgical mortality: Fifteen of the 56 patients (27%) who underwent aneurysmectomy died within 30 days of surgery. Nine of these 15 (60%) underwent operation within 4 weeks after infarction. The surgical mortality of this group was much higher than those who underwent operation later: 9 of 17 (53%) vs 6 of 39 (15%) ($p < 0.05$). Of the 15 patients who died, 13 (87%) died at the time of surgery or within 1 week after surgery. Ten of 13 patients died as a result of pump failure and 2 from refractory ventricular arrhythmias. Two patients died suddenly out of hospital.

Additional surgical procedures: In 12 of 15 nonsurvivors (80%) and 36 of 41 survivors (88%), respectively, 2.1 ± 0.6 (mean ± standard deviation) and 2.0 ± 0.7 bypass grafts were placed. Mitral valve replacement was performed in 3 nonsurvivors (20%) and in 6 survivors (15%). None of these differences was significant.

Residual myocardial index: The residual myocardial index of the whole group ranged from 29 to 71%. In the 15 nonsurvivors the index ranged from 29 to 68% (mean 38 ± 8.5%) (Fig. 3). The index of the 41 survivors ranged from 40 to 71% (mean 53 ± 7.8%) ($p < 0.001$ vs nonsurvivors).

All but 1 of the 15 nonsurvivors had an index of less than 40%. One patient had an index of 68%; this patient had a circumscript but large posterobasal aneurysm and died soon after operation from intractable ventricular arrhythmias.

Clinical improvement: The functional class (New York Heart Association[27]) after surgery was assessed in 29 patients who underwent operation primarily for congestive heart failure. The mean functional class was 3.7 ± 0.5 preoperatively and decreased to 2.3 ± 0.7 postoperatively ($p < 0.001$) (Fig. 4). Nineteen patients improved by 1 functional class and 9 by 2 functional classes. One patient in class IV improved by 3 functional classes.

Discussion

Because aneurysmectomy can lead to relief of symptoms in patients with an LV aneurysm, various invasive measures have been examined for their prognostic value. Of these, the size and function of the nonaneurysmal or residual myocardium has recently been shown to be very useful. Noninvasive determination of the residual myocardium may be clinically important in managing patients with LV aneurysm. Dillon et al[28] using M-mode echocardiography, showed that the LV dimension at the level of the base and papillary muscles could provide information about a patient's suitability for aneurysmectomy. Two-dimensional echo,

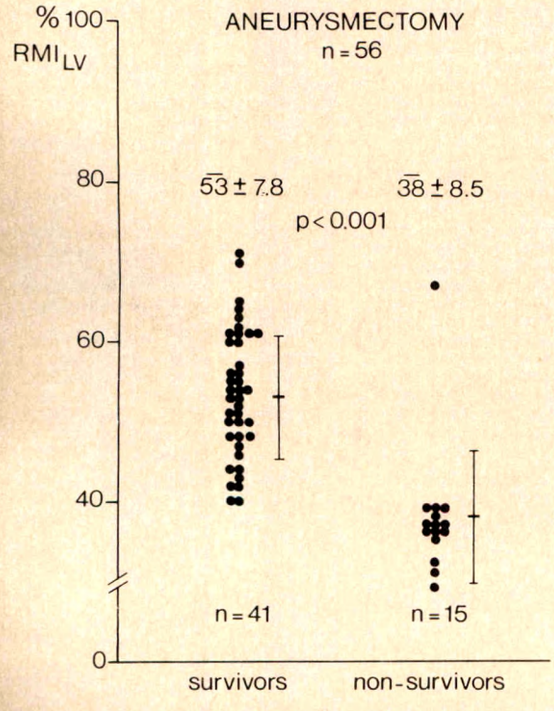

FIGURE 3. Comparison of the residual myocardial index of the left ventricle (RMI_{LV}) with surgical outcome in 56 patients who underwent aneurysmectomy. Except for 1 patient there is a sharp separation between survivors and nonsurvivors. Values are mean ± standard deviation.

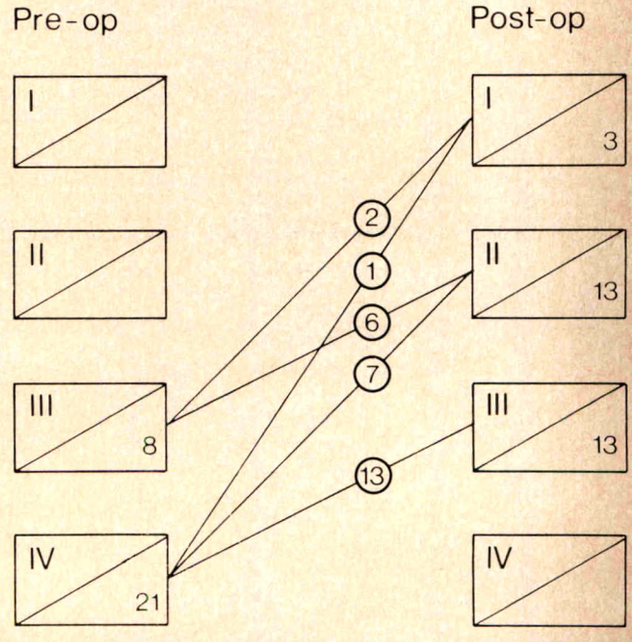

FIGURE 4. Preoperative and postoperative functional class (New York Heart Association criteria) of the 29 patients who underwent operation primarily for congestive heart failure. All patients improved by at least 1 functional class.

in contrast, permits study of the entire LV wall in detail, and therefore is ideally suited for noninvasive assessment of the residual myocardium. Unique information can be obtained about the ventricular septum. This part of the left ventricle is very often involved in an aneurysm and is often obscured on cineangiography by an apical aneurysm. Moreover, the method proposed was applicable in all of our patients.

Surgically mortality: Fifteen patients died after aneurysmectomy. This mortality rate is somewhat higher than that recently reported.[12] This can be explained by the urgent nature, i.e., soon after infarction, of reconstruction in 9 of these patients (67%). In patients undergoing aneurysmectomy soon after infarction the mortality rate is reported to be as high as 50%.[16,19,20] Although mitral valve replacement, in this respect, is usually associated with a high mortality, this additional procedure was not related to the mortality rate in our population.[29] Additional bypass grafting also was not related to the mortality rate. This is consistent with the results of Lee et al.[21] The prognostic value of the extent of coronary artery disease is still controversial.[14,21] The number of bypass grafts in our nonsurvivors was not significantly higher (2.1 ± 0.6 vs 2.0 ± 0.7).

Residual myocardium: Barrett et al[30] reported that an index of the residual myocardium assessed by 2 apical cross sections could predict the 6-month mortality in medically treated patients. Their index was highly related to the presence or absence of congestive heart failure. They could not precisely define the lower limit of surgically acceptable residual myocardium owing to the limited number of patients (12). Except for 1 patient, all of the nonsurvivors in our group had a residual myocardium index of the left ventricle of 39% or less. Thus, the lower limit of the residual myocardium index to survive surgical resection of an aneurysm was 40%. These results must be confirmed in a prospective study.

Relation Between Heart Rate and QT Interval in Exercise-Induced Myocardial Ischemia

MASSIMO ROMANO, MD, TERESA Di MARO, MD, GIOVANNI CARELLA, MD, MARIA ROSARIA COTECCHIA, MD, GIUSEPPE FERRO, MD, and MASSIMO CHIARIELLO, MD

The relation between heart rate and QT interval during dynamic upright exercise on a bicycle ergometer was investigated in control subjects (n = 18) and in patients with coronary artery disease (CAD), stable angina on effort, and angiographically documented significant coronary stenoses (n = 23). Both groups had a significant negative linear relation between heart rate and QT, with a higher correlation coefficient in control subjects (r = −0.78) than in patients with CAD (r = −0.64). This response may be a result of the nonhomogeneous response to ischemia in patients with CAD, particularly with regard to the different impact of exercise-induced ischemia.

When the 2 regression lines were compared, a flatter slope was found in the CAD group ($p < 0.001$) as a consequence of a faster decrease in the QT-increasing rate in control subjects. It is suggested that in control subjects exercise-induced increase in adrenergic tone causes a rapid and relevant decrease in QT-interval duration. In the CAD group, exercise-induced ischemia relatively prolonged the QT interval; this may have been the result of an impairment of myocardium in response to catecholamines release during exercise or the consequence of a direct effect of exercise-induced ischemia prolonging the duration of myocardial tension. **(Am J Cardiol 1985;56:861–862)**

Exercise induces several changes in the QRS-T pattern in patients with coronary artery disease (CAD), but their significance is not fully understood. The assumption that in the ischemic heart, electrical systole as measured by the QT interval (reflecting within limitation the duration of depolarization and repolarization[1]) is prolonged, remains controversial.[2–5]

Methods

Forty-one male volunteers investigated for chest pain were enrolled in the study. They underwent diagnostic coronary angiography. Eighteen patients, mean age (± standard error of the mean) 51 ± 4 years (range 37 to 59), had normal coronary arteries and they served as control subjects. The other 23 subjects, mean age 53 ± 4 years (range 35 to 60), had 70% or greater stenosis of at least 1 major coronary artery. Old myocardial infarction (older than 8 months) was present in 6. All of these CAD patients had positive stress test responses (significant ST depression[3] with chest pain or dyspnea or both). Medical treatment was progressively reduced and discontinued at least 1 week before stress test. Upright exercise was performed in the morning on a bicycle ergometer, with an initial work load of 50 W/min, and increased stepwise by 25 W/min every 2 minutes. Exercise end points were chest pain or dyspnea, 3 mm of ST depression below the value of rest, or attainment of maximal heart rate (HR). A standard 12-lead electrocardiogram was recorded at rest, at each step, at peak exercise and every minute during recovery at a paper speed of 25 mm/s using Marquette CASE equipment. This system minimizes baseline fluctuations of the electrocardiogram and facilitates QT measurement. QT was measured blindly by a trained cardiologist on lead II on 4 beats and averaged; mean HR was derived from the RR interval preceding each considered beat. To avoid miscalculation of QT because of P- or U-wave inclusion,[6] the end of the T wave was measured, whenever necessary, at the intersection between the isoelectric line and the tangential to the terminal limb of the T wave.[7] The correlation between HR and QT was sought by linear regression analysis,[8] considering QT and HR collected at each exercise step; data from the rest and recovery period were excluded. There were 69 entries for control subjects (3 to 4 per subject) and 71 for CAD patients (range 2 to 4). Differences between the regression lines were analyzed by the appropriate t test.[8] In control subjects, mean exercise tolerance was greater; therefore, we excluded data collected in control subjects for workloads greater than 125 W/min, the maximal load attained by CAD patients.

Results

The intraobserver error for QT-interval measurement was estimated as 4 ms, or approximately 1% of the mean QT interval. Baseline, data at rest were similar (mean ± standard deviation of HR, QT and QTc in control subjects and CAD patients were: 82 ± 11, 338 ± 27, 394 ± 29; 78 ± 10, 348 ± 23 and 395 ± 21, respectively). There was a significant correlation between HR and QT in the 18 control subjects: QT(ms) = 451 − 1.36 HR, r = −0.78, $p < 0.001$ (Fig. 1). A significant correlation between QT and HR was also found in the 23 CAD pa-

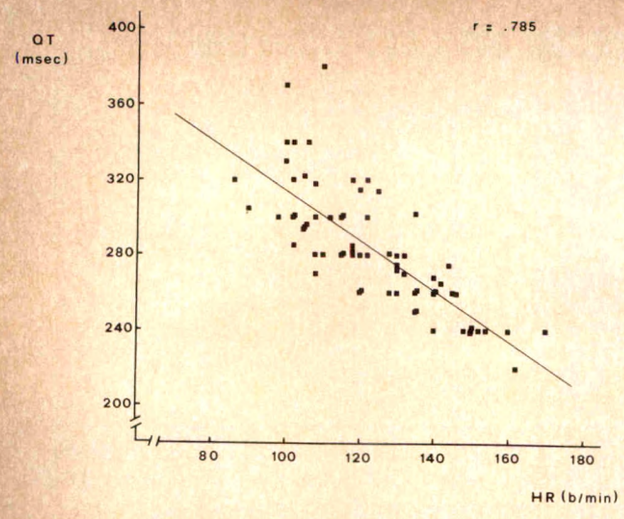

FIGURE 1. Relation between heart rate (HR) and QT interval (QT) during exercise in control subjects (n = 18). b = beats.

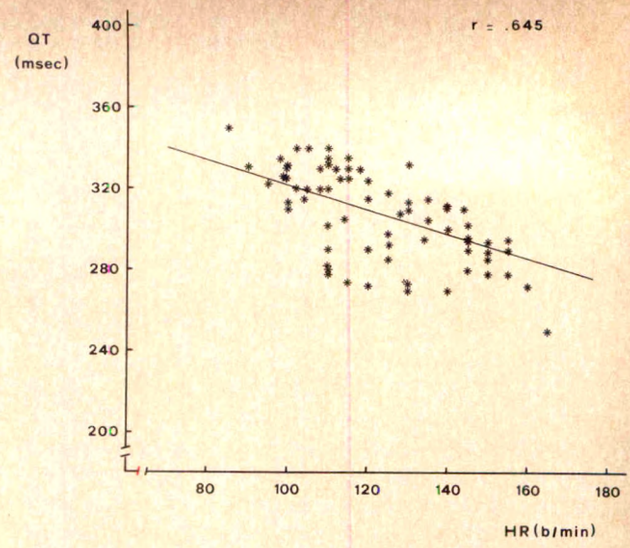

FIGURE 2. Relation between heart rate (HR) and QT interval (QT) during exercise in patients with coronary artery disease (n = 23). b = beats.

tients: QT(ms) = 396 − 0.73 HR, r = −0.64, p <0.001 (Fig. 2). However, the slopes of 2 regressions differed significantly (F = 12, p <0.001); this difference suggested that in CAD patients, similar increases in HR induce smaller decreases in QT duration.

Discussion

HR is an important determinant of the QT interval duration. The exercise-induced QT shortening is related not only to the increase in HR but also to the independent catecholamine activity.[9,10] In the present study, during exercise, QT decreased linearly while HR increased in normal control subjects as well as in CAD patients; however, the rate of QT shortening with HR increase was higher in control subjects than in CAD patients. This finding might be related to exercise-induced myocardial ischemic QT prolongation when the duration of myocardial tension was increased[11] or it may be related to an impairment in cardiac response to exercise-induced catecholamine release.[12,13] Moreover, β-adrenergic blockade was observed to blunt the QT changes in relation to HR variations during exercise.[10] In our study, the HR-QT correlation coefficient was smaller in CAD patients than in control subjects; this may be the result of nonhomogeneous development of myocardial ischemia during exercise; only ischemic regions will have an impaired responsiveness to catecholamines and the QT response to exercise will be relatively erratic. Since the more strenuous the exercise the greater the enhancement in sympathetic activity,[14] the larger difference between the 2 groups in HR-QT relation at the highest level of workload is the consequence of the greater catecholamine-induced QT reduction in control subjects compared with CAD patients. In these CAD patients, sensitivity to catecholamines of ischemic myocardium is reduced and QT interval decreases less. We studied well defined, selected populations (normal subjects and CAD patients with abnormal stress test); therefore, in a less defined, mixed population the effect of HR on QT may be less striking.

Effects of Oral Amiodarone on Rate-Dependent Changes in Refractoriness in Patients with Wolff-Parkinson-White Syndrome

PEDRO BRUGADA, MD, and HEIN J.J. WELLENS, MD

The refractory periods during cardiac pacing were studied in 13 patients with the Wolff-Parkinson-White syndrome. The right atrial and right ventricular refractory periods and refractory period of the accessory pathway (anterogradely and retrogradely) were studied at 2 pacing cycle lengths before and after therapy with oral amiodarone (8,400 to 11,200 mg given in 4 to 6 weeks). The right atrial and right ventricular effective refractory period shortened significantly when the pacing rate was increased during the control study, and also after oral amiodarone administration. The anterograde and retrograde effective refractory period of the accessory pathway also shortened significantly at control study, but not during treatment with oral amiodarone. This indicated that amiodarone blunted the rate-dependent shortening in the refractory period of the accessory pathway. The rate-dependent increase in refractoriness of the accessory pathway could not be predicted or determined in all patients. In 5 patients a rate-dependent increase in the effective refractory period of the accessory pathway was observed in the anterograde direction and in 3 patients in the retrograde direction while they were receiving oral amiodarone therapy. When these data were correlated with the mode of induction and termination of tachycardia, however, a possible effect was found in only 1 patient. Further investigation of new antiarrhythmic drugs should include the development of components resulting in a reliable and predictable increase in refractoriness when the heart rate increases. This would result in prompt termination of reentrant tachycardia by creating block for the circulating impulse.

(Am J Cardiol 1985;56:863–866)

In the human heart the atrial, ventricular and His-Purkinje tissues react with a shortening of their refractory period when the heart rate increases during cardiac pacing. In contrast, the refractory period of the atrioventricular (AV) node lengthens during a pacing-induced increase in cardiac frequency.[1,2] In patients with the Wolff-Parkinson-White syndrome (WPW) who frequently suffer from either a circus movement tachycardia or atrial fibrillation, the relation between heart rate and the duration of the effective refractory period of the accessory pathway is clinically important. The duration of the refractory period of the accessory pathway can decrease, increase or stay the same during a pacing-induced increase in heart rate.[3] In WPW syndrome, when heart rate increases, it would be desirable to have lengthening of the refractory period of the accessory AV pathway, which determines the ventricular rate during atrial fibrillation and of the tissues incorporated in the circuit of circus movement tachycardia. This would protect the ventricle against very high ventricular rates during atrial fibrillation and facilitate spontaneous termination of circus movement tachycardia. Lengthening of the duration of the refractory period on increasing the heart rate would therefore be a very desirable effect of antiarrhythmic drugs. We report on the effects of amiodarone on rate-dependent changes in refractory periods in 13 patients with WPW syndrome.

Values are in milliseconds.

Am = amiodarone; ANTERP = anterograde effective refractory period of the accessory pathway; C = control; PCL = pacing cycle length; RAERP = right atrial effective refractory period; RAFRP = right atrial functional refractory period; RETERP-AP = retrograde effective refractory period of the accessory pathway; RVERP = right ventricular effective refractory period; ShPCL-AP = shortest atrial pacing cycle length with 1-to-1 conduction over the accessory pathway.

functional refractory period are given elsewhere.[3] Refractory periods of right atrium and right ventricle and anterograde and retrograde conduction and refractory period of the accessory pathway were studied by the extrastimulus technique using 3 pacing cycle lengths. At least 2 of the 3 pacing cycle lengths were the same in all patients in the two studies, allowing comparison of results. Regular atrial pacing at increasing rates was also performed to determine the shortest cycle length with 1-to-1 anterograde conduction over the accessory pathway. The anterograde refractory period of the accessory pathway was determined using an atrial site close to the atrial insertion of the accessory pathway. Patients in whom the anterograde refractory period of the accessory pathway could not be determined exactly, because it was shorter than the functional refractory period of the atrium, are not included in this study. In general, the duration of the refractory period of the AV node could not be determined in the patients studied.

Statistical analysis was performed using the paired and unpaired Student t test for continuous variables and the chi-square test for discrete variables. A p value <0.05 was considered significant.

Results

Table I gives the values for the right atrial (RA) effective and functional refractory period, the right ventricular (RV) refractory period, and the anterograde and retrograde effective refractory period of the accessory pathway before and during treatment with oral amiodarone. Results are given at 2 pacing cycle lengths. Also, the shortest atrial pacing cycle length followed by 1-to-1 anterograde conduction over the accessory pathway is shown.

Right atrium: For the whole group of patients the mean difference between pacing cycle length 1 and 2 was 75 ms, or 35 beats/min (mean 94 vs 129 beats/min). At control study the mean duration of the RA effective refractory period at pacing cycle length 1 was 228 ± 20 ms, vs 244 ± 20 ms during oral amiodarone ($p < 0.05$), and 218 ± 28 ms vs 236 ± 25 ms at pacing cycle length 2 (difference not significant [NS]). A rate-dependent lengthening of the RA effective refractory period was observed in 2 patients at control study (10 to 20 ms) and in 3 patients during oral amiodarone therapy (10 to 30 ms). Two patients had no rate-dependent change in the duration of the RA effective refractory period at control study, and 2 patients had no change during oral amiodarone treatment. Amiodarone prolonged significantly the duration of the RA effective refractory period at pacing cycle length 1, but not at pacing cycle length 2. Therefore, no significant change occurred in the rate-dependent behavior of the RA effective refractory period after amiodarone.

The mean RA functional refractory period was 264 ± 29 and 255 ± 26 ms at control study at pacing cycle length 1 and 2, respectively, and 291 ± 29 and 280 ± 26 ms after oral amiodarone administration. Amiodarone prolonged significantly the RA functional refractory period at pacing cycle lengths 1 and 2 ($p < 0.05$ and $p < 0.02$). The mean RA functional refractory period shortened significantly with oral amiodarone when the pacing cycle length was shortened ($p < 0.05$). Three patients showed an increase in the duration of the RA functional refractory period when the pacing cycle

length was shortened during control study (range 10 to 30 ms) and 2 patients during oral amiodarone (range 10 to 20 ms) (NS).

Right ventricle: The RV effective refractory period decreased significantly at control study when the pacing cycle length was shortened (231 ± 21 vs 210 ± 15 ms at pacing cycle length 1 and 2, respectively, $p < 0.001$) and also during treatment with oral amiodarone (243 ± 16 vs 220 ± 18 ms, $p < 0.01$). The RV effective refractory period did not change significantly during treatment with oral amiodarone at any pacing cycle length. No patient showed a rate-dependent increase in RV effective refractory period at control study, and only 1 patient after oral amiodarone (20 ms). The lack of prolongation of the RV effective refractory period is in contrast with previous observations.[4] This may be a dose-related phenomenon.

Accessory pathway: The duration of the anterograde effective refractory period of the accessory pathway decreased significantly at control study when the pacing cycle length was shortened (285 ± 34 vs 267 ± 31 ms, $p < 0.01$), but not during treatment with oral amiodarone (346 ± 80 vs 341 ± 89 ms). Amiodarone prolonged significantly the duration of the anterograde effective refractory period of the accessory pathway at both pacing cycle length 1 and 2 ($p < 0.01$ and $p < 0.01$, respectively). Therefore, when the whole group of patients was considered, amiodarone hampered a rate-dependent shortening of the anterograde refractory period of the accessory pathway. A rate-dependent lengthening of the anterograde effective refractory period of the accessory pathway was present in 1 patient at control study and in 5 patients during oral amiodarone therapy (10 to 200 ms). Another patient showed no rate-related changes in duration of the anterograde refractory period of the accessory pathway while receiving amiodarone ($p < 0.05$, control vs amiodarone).

At control study the retrograde effective refractory period of the accessory pathway shortened significantly when the pacing cycle length was shortened (308 ± 63 vs 282 ± 58 ms, $p < 0.01$), but not during treatment with amiodarone (338 ± 60 vs 357 ± 89 ms). Amiodarone significantly prolonged the duration of the retrograde effective refractory period of the accessory pathway determined at pacing cycle length 1 or 2. No patient had rate-dependent lengthening of the retrograde effective refractory period of the accessory pathway during control study, but 3 patients had it during treatment with oral amiodarone. For the whole group of patients, therefore, amiodarone lessened the rate-dependent shortening in the retrograde effective refractory period of the accessory pathway present during control study.

The shortest cycle length followed by 1-to-1 anterograde conduction over the accessory pathway increased significantly after amiodarone treatment (285 ± 73 vs 376 ± 115 ms, $p < 0.05$).

Observations during circus movement tachycardia (Table II): Circus movement tachycardia was induced in 12 patients during control study and in 9 patients during treatment with oral amiodarone. Inability to induce tachycardia after amiodarone was based upon the creation of ventriculoatrial block in the accessory pathway in 2 patients and a long retrograde effective refractory period of the accessory pathway in 1 patient (no. 10). The mean tachycardia cycle length increased significantly after oral amiodarone (307 ± 49 vs 396 ± 60 ms, $p < 0.01$). During control study circus movement tachycardia did not terminate spontaneously in any patient, but tachycardia terminated spontaneously in 6 patients during oral amiodarone treatment.

TABLE II Observations During Circus Movement Tachycardia Before and After Amiodarone

	Control		Amiodarone	
Pt	TCL (ms)	SPT	TCL (ms)	SPT
1	350	–	435	AP
2	360	–	450	AVN
3	385	–	460	–
4	280	–	NI	–
5	280	–	300	AVN
6	270	–	300	Subnodally
7	285	–	NI	–
8	210	–	NI	–
9	255	–	350	AP
10	NI	–	NI	–
11	320	–	460	–
12	340	–	400	–
13	350	–	410	AVN

AVN = atrioventricular node; AP = accessory pathway; NI = not induced; SPT = spontaneous termination; TCL = tachycardia cycle length; – = negative.

The site of block during spontaneous termination of tachycardia on oral amiodarone treatment was the AV node in 3 patients, between the His bundle and the ventricle in 1 patient, and retrogradely in the accessory pathway in 2 patients. Only 1 of the last 2 patients showed a rate-dependent lengthening of the retrograde effective refractory period of the accessory pathway during single test stimulation of the ventricle during oral amiodarone treatment. In the other patients who showed a rate-dependent lengthening of the retrograde effective refractory period of the accessory pathway on amiodarone, tachycardia terminated subnodally (patient 6) or could not be initiated (patient 10).

Discussion

In reentrant tachycardias antiarrhythmic drugs can exert their beneficial effects by preventing the initiating premature beat or by changing the properties of the reentry circuit and affecting the critical balance between conduction velocity and refractoriness required to initiate and sustain reentrant tachycardia. Most antiarrhythmic drugs have marked effects not only on the duration of the refractory period of cardiac tissues, but also on conduction velocity. As a result of the interplay between effects on refractoriness and conduction velocity, antiarrhythmic drugs may prevent tachycardias in some patients but facilitate the occurrence of tachycardia in others. An antiarrhythmic drug with no or minimal effects on conduction velocity, but marked effects on refractoriness in the reentry circuit,

and particularly one that induces a rate-dependent lengthening of refractoriness in the reentry circuit would approach the ideal antiarrhythmic drug against reentry. The rate-dependent lengthening in refractoriness in a part or the whole reentrant circuit would result in prompt termination of tachycardia by creating block in the circuit for the circulating impulse.

Amiodarone is a potent antiarrhythmic drug with marked effects on refractoriness.[4,5] We wondered whether the creation of a rate-dependent lengthening in refractoriness contributed to its antiarrhythmic action. Patients with WPW were chosen because reentry is the mechanism of circus movement tachycardia and determination of the effects of an antiarrhythmic drug on the different components of the reentry circuit is possible.

During a mean rate difference of 35 beats/min during cardiac pacing, amiodarone reduced a rate-dependent shortening in duration of the anterograde and retrograde effective refractory periods of the accessory pathway. Results were statistically significant when the whole patient population was considered. When this information was correlated with the mode of spontaneous termination of circus movement tachycardia in 6 patients while receiving treatment with oral amiodarone, a possible clinical correlation could be demonstrated in only 1 patient. Explanations for these findings are: (1) the inability to initiate circus movement tachycardia in 4 patients while receiving oral amiodarone; (2) the effects of amiodarone on the AV node, making this the weak link in the tachycardia circuit[4]; and (3) the possibility that spontaneous adrenergic discharge during tachycardia counteracts the effects induced by amiodarone on rate-related changes on refractory periods.[6,7] The effects of amiodarone on rate-related changes in refractoriness of the AV node could not be studied in these patients because of anterograde conduction over an accessory pathway.

How to use Catapres-TTS®

Three Dosage Strengths for Individualized Therapy
Titrate to proper dosage with Catapres-TTS® alone

1. Start with #1. Replace with #2 and then #3 when necessary to achieve effective blood pressure control.
2. Catapres-TTS® is usually unaffected by showering or other routine daily activities. For some patients, use of an overlay is occasionally required to maintain adequate skin adherence.
3. Most common side effects are dry mouth and drowsiness, which tend to diminish with time, and mild erythema and pruritus associated with 7-day skin occlusion. Contact dermatitis was observed in 16% of patients (100 of 631) treated for a mean duration of 24 weeks. This condition resolved upon discontinuation of therapy.*

Brief Summary of Prescribing Information

Contraindications: Catapres-TTS® (clonidine) should not be used in patients with known hypersensitivity to clonidine or to any other component of the adhesive layer of the therapeutic system.

Precautions: ***General:*** In patients who have developed localized contact sensitization to Catapres-TTS® (clonidine), substitution of oral clonidine hydrochloride therapy may be associated with development of a generalized skin rash.

In patients who develop an allergic reaction to Catapres-TTS® that extends beyond the local patch site (such as generalized skin rash, urticaria, or angioedema) oral clonidine hydrochloride substitution may elicit a similar reaction.

As with all antihypertensive therapy, Catapres-TTS® should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease, or chronic renal failure.

Withdrawal: Patients should be instructed not to discontinue therapy without consulting their physician. Sudden cessation of clonidine treatment has resulted in subjective symptoms such as nervousness, headache and sweating, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine concentrations in the plasma, but such occurrences have usually been associated with previous administration of high oral doses (exceeding 1.2 mg/day) and/or with continuation of concomitant beta-blocker therapy. Rare instances of hypertensive encephalopathy and death have been reported.

An excessive rise in blood pressure following Catapres-TTS® discontinuance can be reversed by administration of oral clonidine or by intravenous phentolamine. If therapy is to be discontinued in patients receiving beta-blockers and clonidine concurrently, beta-blockers should be discontinued several days before cessation of Catapres-TTS® administration.

Perioperative Use: As with oral clonidine therapy, Catapres-TTS® therapy should not be interrupted during the surgical period. Blood pressure should be carefully monitored during surgery and additional measures to control blood pressure should be available if required. Physicians considering starting Catapres-TTS® therapy during the perioperative period must be aware that therapeutic plasma clonidine levels are not achieved until 2 to 3 days after initial application of Catapres-TTS®.

Information for Patients: Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of a potential sedative effect of clonidine. Patients should be cautioned against interruption of Catapres-TTS® therapy without a physician's advice. Patients should be advised that if the system begins to loosen from the skin after application, the adhesive overlay should be applied directly over the system to ensure good adhesion over its 7-day lifetime. Instructions for using the system are provided. Patients who develop moderate or severe erythema and/or localized vesicle formation at the site of application, or a generalized skin rash, should consult their physician promptly about the possible need to remove the patch.

Drug Interactions: If a patient receiving clonidine is also taking tricyclic antidepressants, the effect of clonidine may be reduced, thus necessitating an increase in dosage. Clonidine may enhance the CNS-depressive effects of alcohol, barbiturates or other sedatives. Amitriptyline in combination with clonidine enhances the manifestation of corneal lesions in rats.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a 132-week oral carcinogenicity study in rats, clonidine hydrochloride produced no carcinogenic effects at doses up to 300 times the maximum recommended human dose of Catapres-TTS® on a mg/kg weight basis.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Reproduction studies performed in rabbits at doses up to 3.1 times the maximum recommended daily human dose of Catapres-TTS® have revealed no evidence of impaired fertility or harm to the fetus due to clonidine hydrochloride. Studies in rats and mice revealed that doses of 500 mcg/kg/day and higher are embryotoxic. One rat study at doses of 15 mcg/kg/day (0.33 times the maximum recommended daily human dose) exhibited embryotoxicity. There are no adequate and well-controlled studies in pregnant women. Although animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: As clonidine is excreted in human milk, caution should be exercised when Catapres-TTS® (clonidine) is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children below the age of 12 have not been established.

Adverse Reactions: Most systemic adverse effects during therapy with Catapres-TTS® (clonidine) have been mild and have tended to diminish with continued therapy. In a 3-month, multiclinic trial of Catapres-TTS® in 101 hypertensive patients, the most frequent systemic reactions were dry mouth (25 patients) and drowsiness (12 patients).

Transient localized skin reactions, primarily localized pruritus occurred in 51 patients. Twenty-six patients experienced localized erythema. This erythema and pruritus were more common in patients utilizing an adhesive overlay for the entire 7-day treatment period. Allergic contact sensitization to Catapres-TTS® was observed in 5 patients.

In additional clinical experience, contact dermatitis was observed in 100 of 631 patients (about 16 in 100) treated for a mean duration of 24 weeks.

The following less frequent adverse experiences were also reported in patients involved in the multiclinic trial with Catapres-TTS®.

Gastrointestinal: Constipation (1 patient); nausea (1); and change in taste (1).

Central Nervous System: Fatigue (6 patients); headache (5); lethargy (3); sedation (3); insomnia (2); dizziness (2); and nervousness (1).

Genitourinary: Impotence/sexual dysfunction (2 patients).

Dermatological: Localized vesiculation (7 patients); hyperpigmentation (5); edema (3); excoriation (3); burning (3); papules (1); throbbing (1); blanching (1); and generalized macular rash (1).

In additional clinical experience involving 3539 patients, less common dermatologic reactions have occurred, where a causal relationship to Catapres-TTS® was not established: maculopapular skin rash (10 cases); urticaria (2 cases); angioedema involving the face (2 cases), one of which also involved the tongue.

Oro-otolaryngeal: Dry throat (2 patients).
In long experience with oral clonidine hydrochloride, the most common adverse reactions have been dry mouth (about 40%), drowsiness (about 35%) and sedation (about 8%). In addition, the following adverse reactions have been reported less frequently:

Gastrointestinal: Nausea and vomiting, about 5 in 100 patients; anorexia and malaise, each about 1 in 100; mild transient abnormalities in liver function tests, about 1 in 100; parotitis, rarely.

Metabolic: Weight gain, about 1 in 100 patients; gynecomastia, about 1 in 1000; transient elevation of blood glucose or serum creatine phosphokinase, rarely.

Central Nervous System: Nervousness and agitation, about 3 in 100 patients; mental depression, about 1 in 100 and insomnia, about 5 in 1000. Vivid dreams or nightmares, other behavioral changes, restlessness, anxiety, visual and auditory hallucinations and delirium have been reported.

Cardiovascular: Orthostatic symptoms, about 3 in 100 patients; palpitations and tachycardia, and bradycardia, each about 5 in 1000. Raynaud's phenomenon, congestive heart failure, and electrocardiographic abnormalities (i.e. conduction disturbances and arrhythmias) have been reported rarely.

Dermatological: Rash, about 1 in 100 patients; pruritus, about 7 in 1000; hives, angioneurotic edema and urticaria, about 5 in 1000; alopecia, about 2 in 1000.

Genitourinary: Decreased sexual activity, impotence and loss of libido, about 3 in 100 patients; nocturia, about 1 in 100; difficulty in micturition, about 2 in 1000; urinary retention, about 1 in 1000.

Other: Weakness, about 10 in 100 patients; fatigue, about 4 in 100; headache, and discontinuation syndrome, each about 1 in 100; muscle or joint pain, about 6 in 1000 and cramps of the lower limbs, about 3 in 1000. Dryness, burning of the eyes, dryness of the nasal mucosa, pallor, weakly positive Coombs' test, increased sensitivity to alcohol and fever have been reported.

How Supplied: Catapres-TTS®-1 (clonidine), Catapres-TTS®-2 (clonidine) or Catapres-TTS®-3 (clonidine) is supplied as 4 pouched systems and 4 adhesive overlays per carton.

Catapres-TTS®-1 or Catapres-TTS®-2 is supplied in a shipper of 3 cartons.

Consult package insert before prescribing.

Evaluation by Serial Electrophysiologic Studies of an Abbreviated Oral Loading Regimen of Amiodarone

ELEANOR E. KENNEDY, MD, LYNDA E. ROSENFELD, MD, CRAIG A. McPHERSON, MD, and WILLIAM P. BATSFORD, MD

Optimal loading and maintenance regimens for amiodarone are undefined. Serial electrophysiologic testing was used in 25 patients with ventricular tachycardia to assess the adequacy of a 1-week oral loading regimen at 1,200 mg/day, to modify maintenance dosing at the conclusion of loading, and to evaluate the appropriateness of maintenance dosing after 2 months of therapy. During the loading period, highly significant ($p < 0.001$) increases occurred in the AH interval (88 ± 22 vs 120 ± 31 ms), HV interval (49 ± 10 vs 61 ± 11 ms), AV nodal Wenckebach cycle length (390 ± 92 vs 537 ± 147 ms), ventricular refractory period (247 ± 17 vs 276 ± 23 ms), mean ventricular tachycardia cycle length (254 ± 38 vs 298 ± 52 ms) and return cycle length (294 ± 55 vs 360 ± 87 ms). Ventricular tachycardia inducibility decreased in only a minority of cases, and when observed in association with a more than 10% increase in ventricular refractory period, resulted in a lower maintenance dose. After 2 months of maintenance therapy no additional change occurred in any of these parameters except for an increase in ventricular tachycardia cycle length (298 ± 52 vs 330 ± 65 ms, $p < 0.017$). Ventricular tachycardia inducibility again showed no consistent response. It is concluded that patients can be discharged after 1 week of therapy with oral amiodarone loading at 1,200 mg/day and that maintenance dosing modified by electrophysiologic assessment results in steady perpetuation of the cardiac amiodarone effect, as indicated by the time course of change in electrophysiologic variables consistently affected.

(Am J Cardiol 1985;56:867–871)

Because of its unusual pharmacokinetic characteristics,[1–4] optimal dosing with amiodarone is controversial. In particular, oral loading regimens have varied widely, with doses ranging from 600 to 1,400 mg/day and duration of loading ranging from 1 to 4 weeks.[5–9] This problem is fostered by the difficulty in applying standard methods of judging antiarrhythmic effect to amiodarone.[7–13] The effects of oral amiodarone on electrophysiologic variables have been well described[7,12–16] and are a direct bioassay of cardiac drug effect. The purposes of this prospective study were to determine whether a relatively abbreviated 1-week oral loading regimen resulted in substantial electrophysiologic change, and to determine whether, as opposed to a fixed dosing schedule, individual discharge dosing could be appropriately modified on the basis of electrophysiologic findings after the loading period.

Methods

Patients: The study group consisted of 25 consecutive patients with ventricular arrhythmias unrelated to acute myocardial infarction or other reversible phenomena and in whom control electrophysiologic study could be performed within 3 weeks of the start of amiodarone therapy. Clinical characteristics are detailed in Table I. All patients with nonsustained ventricular tachycardia (VT) had either syncope in association with nonsustained VT on Holter monitoring or long and frequent asymptomatic runs of nonsustained VT on electrocardiographic monitoring.

Amiodarone dosing regimen (Table II): Patients received an oral loading dose of 1,200 mg/day for 8 ± 2 days (mean ± standard deviation). An 800-mg loading dose, as well as a reduced maintenance dose, was used for patients 3 and 12 because of their weight (less than 55 kg). Patients were then discharged receiving reduced doses of amiodarone, most often given at 800 mg/day. Discharge doses of 400 to 600 mg/day were considered for patients with clinical sustained VT or nonsustained VT if at least 1 of the following criteria were met: (1) a gross decrease in VT inducibility accompanied by more than 10% increase in the ventricular refractory period (patients 2, 13, and 14), (2) a noninducible response in association with the clinical diagnosis of nonsustained VT (patients 13, 14 and 24), and (3) intolerable side effects (patient 3 and 13). Patient 1, whose clinical arrhythmia was nonsustained VT, was also discharged receiving 600 mg/day because his maximal response of 5 consecutive complexes of VT barely met our criteria for induced nonsustained VT (see later). All patients with primary ventricular fibrillation received 800 mg/day. After 2 months of therapy (69 ± 14 days), the dosage was reduced further (408 ± 158 mg/day) for long-term treatment.

Electrophysiologic studies: All patients underwent electrophysiologic evaluation in the control state 4 or more half-lives after discontinuation of all antiarrhythmic agents, after 1 week (8 ± 2 days) of oral amiodarone loading, and after

Nonsustained ventricular tachycardia	11
Previous drug trials failed	3.3 ± 1.7

2 months (69 ± 14 days) of outpatient maintenance therapy. Patients were studied in the postabsorptive nonsedated state after they gave written informed consent. Multielectrode catheters were inserted percutaneously and positioned under fluoroscopic guidance. Recording and pacing sites included the high right atrium, His bundle area, right ventricular apex and coronary sinus. Surface leads I, II and V_1 were displayed simultaneously with intracardiac tracings and recorded on a VR-12 (Electronics for Medicine) recorder at a paper speed of 50 to 150 mm/s. Cardiac stimulation was performed with a programmed constant-current stimulator (World Precision Instruments) using rectangular pulses 1 ms in duration, delivered at twice diastolic threshold or 1.5 mA, whichever was higher.

Sinus cycle length, corrected sinus node recovery time, sinoatrial conduction time, AH and HV intervals, and refractory periods of the right atrium and right ventricle were measured according to standard techniques.[17,18] The maximal atrioventricular nodal Wenckebach cycle length was determined by incremental atrial pacing. The ventricular stimulation protocol consisted of (1) single, double and triple extrastimuli during spontaneous rhythm and at 2 or more paced cycle lengths, (2) single and double extrastimuli following a drive train with abrupt short-to-long cycle length changes,[19] and (3) brief bursts of rapid right ventricular pacing. The endpoints of stimulation were (1) induction of sustained VT, (2) induction of rapid nonsustained VT (mean cycle length 250 ms or less) of at least 10 consecutive complexes, or (3) ventricular refractoriness.[20] VT mean cycle length and return cycle length, the latter defined as the interval from the ventriculogram of the last programmed extrastimulus to the first VT complex, were measured in patients with induced VT lasting at least 5 consecutive complexes at all 3 studies.

Definition of induced ventricular responses: Sustained VT was defined as VT requiring pacing or external cardioversion for termination. Nonsustained VT was defined as VT of at least 5 consecutive complexes and reverting spontaneously to supraventricular rhythm. A noninducible response occurred when fewer than 5 consecutive VT complexes could be induced after completion of the stimulation protocol. A decrease in inducibility was defined as a change from sustained VT to either nonsustained VT or a noninducible response, or a change from nonsustained VT to a noninducible response.

Statistical methods: Analysis was performed using a Student 2-tailed paired t test. In accordance with the Bonferroni correction for multiple comparisons,[21] $p < 0.017$ was required for statistical significance. All values are given as mean ± standard deviation in milliseconds unless otherwise specified.

Results

The effects of amiodarone on electrophysiologic variables are summarized in Table III. There is a con-

All values are expressed as mean ± standard deviation in milliseconds.
* $p < 0.05$, but not significant by Bonferroni correction requiring $p < 0.017$ for 3 comparisons.
ARP = atrial refractory period; C = Control; CSNRT = corrected sinus node recovery time; NS = not significant; RCL = return cycle length; SACT = sinoatrial conduction time; SCL = sinus cycle length; VRP = ventricular refractory period; VTCL = ventricular tachycardia cycle length; WCL = Wenckebach cycle length.

tinuous trend toward an increase in sinus cycle length over the treatment period (Fig. 1), which reaches statistical significance when the control and 2-month studies are compared ($p < 0.001$). There were no significant changes in corrected sinus node recovery time or sinoatrial conduction time (Fig. 1).

In contrast, the AH and HV intervals and Wenckebach cycle length increased ($p < 0.001$) during the loading period and remained stable thereafter during the maintenance phase (Fig. 2). Refractory periods of the atrium and ventricle also lengthened during amiodarone therapy (Fig. 3), and exhibited the same pattern as that followed by the AH and HV intervals and the Wenckebach cycle length.

VT cycle length increased after 1 week of amiodarone loading ($p < 0.001$), with a further increment ($p < 0.017$) occurring from 1 week to 2 months (Fig. 4). The return cycle length followed the predominant pattern, with a significant increase during loading, which was sustained at the same level during maintenance therapy.

Assessment of overall (Fig. 5) and individual (Table II) response to programmed right ventricular stimulation revealed no consistent pattern of change in inducibility. Although some patients showed a decrease in the level of VT inducibility with amiodarone relative to the control state, most did not. There was no striking change over time in the proportion of patients who had sustained VT, nonsustained VT or a noninducible response.

Toxicity and efficacy: Two instances of intolerable side effects occurred during loading (gastrointestinal and sinus node dysfunction) and 7 instances occurred during 14 ± 5 months of follow-up: 2 pulmonary, 3 gastrointestinal, 1 neurologic and 1 hepatic. Amiodarone therapy was discontinued in 1 patient with primary ventricular fibrillation, who had an unacceptable proarrhythmic response with a marked increase in the

ease of VT inducibility after 2 months of amiodarone therapy. Of the remaining 24 patients, 19 (79%) have remained free of arrhythmia recurrence.

Discussion

Two conclusions of direct clinical importance regarding amiodarone dosing are suggested by these data. First, significant electrophysiologic effects can be achieved after 1 week of oral loading with 1,200 mg/day. This finding is of clinical relevance because patients have previously been hospitalized for up to 4 weeks for amiodarone loading.[7,9] Because no arrhythmia recurred between 1 week and 2 months of therapy, patients generally can be discharged after a 1-week loading period in the absence of persistent spontaneous and severe arrhythmias.

Second, the extent of electrophysiologic change after loading may be useful in selecting the level of maintenance therapy. A decrease in VT inducibility, which previously has been suggested to have favorable prognostic implications with amiodarone,[22,23] prompted a lower discharge dose when associated with a more than 10% increase in ventricular refractory period. The increase in refractory period was required to lessen the possibility that the decrease in VT inducibility was an artifact of programmed ventricular stimulation nonreproducibility,[20] and to substantiate the role of amiodarone therapy in the decrease in VT inducibility in these individual cases, since amiodarone did not affect VT inducibility with any degree of consistency in the patient group as a whole.

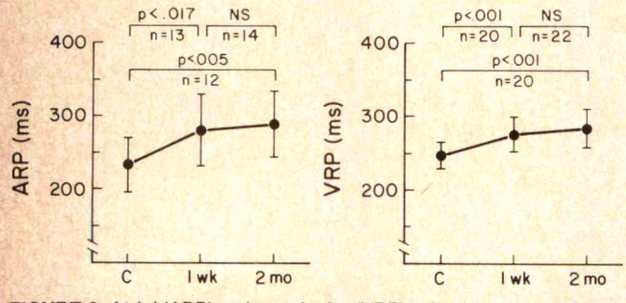

FIGURE 3. Atrial (ARP) and ventricular (VRP) refractory periods in the control state, after 1 week of oral amiodarone loading, and after 2 months of maintenance therapy. NS = not significant.

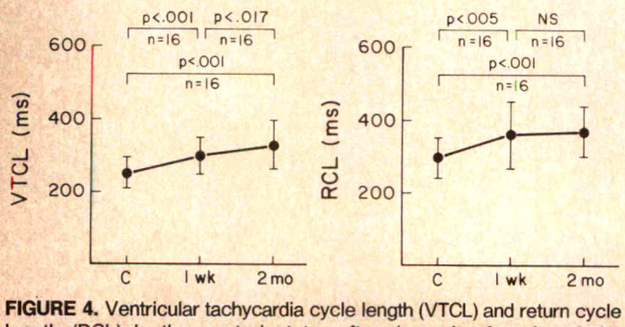

FIGURE 4. Ventricular tachycardia cycle length (VTCL) and return cycle length (RCL) in the control state, after 1 week of oral amiodarone loading, and after 2 months of maintenance therapy. NS = not significant.

Effect of amiodarone on electrophysiologic parameters: Unlike VT inducibility, many electrophysiologic variables were affected in a consistent manner by amiodarone. Sinus cycle length, AH interval, AV nodal Wenckebach cycle length, atrial and ventricular refractory periods and mean VT cycle length all increased, consistent with earlier studies.[7,12–16] The HV interval also lengthened, as observed by some[7,14] but not all previous investigators.[12,13]

With 2 exceptions, all consistently affected variables significantly increased during loading, and these increases were sustained, with no further major change during maintenance therapy. The more continuous increase in sinus cycle length and mean VT cycle length is consistent with observations by other investigators,[11,24] who noted more marked increases in these 2 measurements during chronic oral therapy than during acute intravenous therapy. Whether metabolite effect or slower penetration of a "deeper"[10] physiologic compartment is responsible for these more sustained increases is unknown.

Limitations: At the time of this study we did not have facilities for determining serum amiodarone levels. Comparison between the time courses of electrophysiologic changes and serum levels are ongoing in our laboratory.

The electrophysiologic data concern only the first 2 months of amiodarone therapy, and do not ascertain stable perpetuation of electrophysiologic influence during later maintenance therapy. Nevertheless, the 79% arrhythmia control rate is consistent with clinically meaningful maintenance of amiodarone effect during long-term therapy.

Our findings concerning VT inducibility should be interpreted in the context of the endpoints of our stimulation protocol, which included the induction of

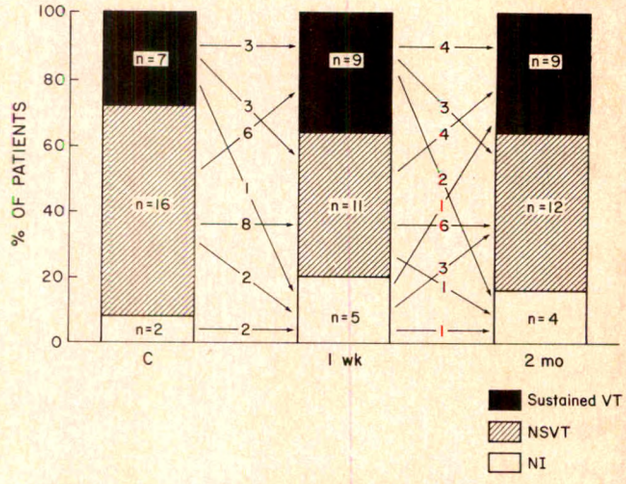

FIGURE 5. Proportion of patients with different inducible ventricular arrhythmias in the control state, after 1 week of amiodarone loading, and after 2 months of maintenance therapy. **Arrows** indicate the number of patients changing levels of inducibility or remaining at the same level of inducibility from 1 electrophysiologic study to the next. NI = no inducible ventricular tachycardia; NSVT = nonsustained ventricular tachycardia; VT = sustained ventricular tachycardia. See text for details.

at least 10 beats of rapid VT. For example, all of the patients with clinical sustained VT who are listed in Table II as having nonsustained VT inducible at control electrophysiologic study did have at least 10 beats of rapid VT, at which point the protocol was terminated. Higher incidences of inducible sustained VT might have resulted had we uniformly persisted until either a sustained arrhythmia or ventricular refractoriness was achieved.

The considerations used in this study to select maintenance dosing are somewhat complex in comparison to a uniform regimen. However, because of the differences in arrhythmia responsiveness and susceptibility to adverse effects, adherence to a fixed amiodarone dosing protocol may not be practical.[25] The clinical outcomes as well as the results of electrophysiologic testing at 2 months suggest that modification of a dosing protocol by electrophysiologic assessment after loading is a reasonable therapeutic alternative.

Spontaneous Termination of Reciprocating Tachycardia Owing to Interaction of Dual Atrioventricular Nodal Pathways in Patients with an Accessory Pathway

KARL-HEINZ KUCK, MD, KLAUS-PETER KUNZE, MD, MICHAEL SCHLUTER, PhD, and WALTER BLEIFELD, MD

Retrospective analysis of the electrophysiologic recordings from 125 consecutive patients with reciprocating tachycardia involving an accessory atrioventricular (AV) pathway suggested, by the mode of spontaneous termination of reciprocating tachycardia, the coexistence of dual AV nodal pathways in 7 patients. Three different modes of spontaneous tachycardia termination were observed. In 2 patients with antidromic tachycardia, termination was a result of AV nodal reentry, preceded by a decrease in retrograde AV nodal conduction. In 3 other patients with antidromic tachycardia, termination occurred after a sudden switch from a slow to a fast AV nodal pathway, leading to conduction block in either the accessory pathway or the His-Purkinje system. In 2 patients with orthodromic tachycardia, termination was caused by a sudden change of anterograde conduction from a fast to a slow AV nodal pathway, eliciting an AV nodal echo beat. The interaction of dual AV nodal pathways within the reentry circuit incorporating the accessory pathway always inhibited sustained reciprocating tachycardia.

(Am J Cardiol 1985;56:872–876)

The most frequent rhythm disorder in patients with the Wolff-Parkinson-White (WPW) syndrome is paroxysmal orthodromic reciprocating tachycardia, which involves the atrioventricular (AV) node in anterograde and the accessory AV pathway in retrograde direction.[1,2] Occasionally, supraventricular tachycardia may be an antidromic reciprocating tachycardia in which the impulse is conducted anterogradely over the accessory pathway and retrogradely over His bundle and AV node.[3]

In cases in which the AV nodal limb of the reentrant circuit consists of multiple conduction pathways, the arrhythmias may become more complex, and the interaction between these pathways and the single accessory AV connection may be important for the initiation and continuation of reentrant tachycardias.[4–6]

We report on the interaction of dual AV nodal pathways in the mechanism of spontaneous termination of reciprocating tachycardia in the WPW syndrome. Various modes of impulse conduction within the AV node during reciprocating tachycardia may lead to early cessation of tachycardia and may prevent sustained tachycardia in these patients.

Methods

Patients: We retrospectively analyzed electrophysiologic studies of 125 consecutive patients with an accessory AV pathway to examine the mode of spontaneous termination of reciprocating tachycardia involving the accessory pathway. In 34 patients (27%) tachycardia terminated spontaneously: in the accessory pathway in 16, in the His-Purkinje system in 4, and by AV nodal involvement in 14 patients. Of these 14 patients, the electrophysiologic study suggested participation of dual AV nodal pathways in the mode of spontaneous tachycardia termination in 7. The records of these 7 patients form the basis of this report. All 7 patients had a history of palpitations. Episodes of nonsustained orthodromic tachycardia had been documented in 2 patients. There were 4 men and 3 women, mean age 38 years. Five patients had the typical electrocardiographic pattern of the WPW syndrome, whereas 2 patients had a normal surface electrocardiogram.

Electrophysiologic study: After patients gave informed, written consent, they were studied in the resting, nonsedated state. They had taken no medication for 48 hours. Using the Seldinger technique, quadripolar catheters were passed through both femoral veins and advanced to the high right atrium, coronary sinus and right ventricular apex. In patient 1 an additional quadripolar catheter was advanced into the left atrium through a patent foramen ovale. In all patients a bipolar catheter was positioned across the tricuspid valve to record His bundle electrograms. Our stimulation protocol has previously been reported.[7] All electrograms were recorded simultaneously on a 16-channel electrocardiograph at a paper speed of 100 mm/s. Stimulus strength was twice diastolic threshold and stimulus duration was 0.5 ms.

Definitions: Conventional definitions were used for refractory periods[8]; the presence of an accessory pathway was diagnosed by standard criteria,[9] as were antidromic or

orthodromic reciprocating tachycardia. The diagnosis of dual AV nodal pathways during basic pacing with the extrastimulus technique and of AV nodal echoes was made according to Denes et al[10] and Rosen et al.[11] A tachycardia was termed nonsustained when more than 3 beats were induced and its duration was less than 30 seconds. When the tachycardia lasted longer than 30 seconds it was termed sustained.

Drug intervention: To study the characteristics of retrograde conduction in patients 3, 4 and 5, with antidromic reciprocating tachycardia, 1 mg of atropine was administered intravenously before repetition of the stimulation protocol.

Patients were followed up for a mean of 11 months.

Results

Patients 1 to 5 had an accessory pathway capable of both anterograde and retrograde conduction, whereas patients 6 and 7 had a concealed accessory pathway.

Characteristics of tachycardia: Basic electrophysiologic data and characteristics of reciprocating tachycardia are summarized in Table I. Sustained tachycardia was not induced in any of our patients. After atropine, tachycardia became sustained in all 3 patients who received the drug.

Dual AV nodal pathways could not be diagnosed with the extrastimulus technique during basic atrial or ventricular pacing in patients 1 to 5, because the anterograde effective refractory period of the accessory pathway was shorter than the anterograde AV nodal refractory period, precluding disclosure of discontinuous AV nodal conduction curves. In patients 6 and 7, atrial pacing with the extrastimulus technique revealed discontinuous anterograde AV nodal conduction curves.

Modes of tachycardia termination: In all patients, the presence of dual AV nodal pathways was suggested by the mode of termination of reciprocating tachycardia. Three different modes of spontaneous termination were observed.

Atrioventricular nodal echo in antidromic tachycardia: Two patients (nos. 1 and 2) with antidromic reciprocating tachycardia revealed long retrograde conduction times (VA interval 290 and 250 ms, respectively) during tachycardia. In both patients exact measurements of retrograde AV nodal conduction time (HA interval) during tachycardia were not possible, since retrograde His potentials were obscured in the ventricular potentials of the His bundle area, with the exception of the tachycardia-initiating beat (Fig. 1). A sudden increase of retrograde conduction time during reciprocating tachycardia, measured by prolongation of the AA interval, led to the appearance of a His potential before onset of the last tachycardia beat. The QRS complex of this beat was narrower and had a different morphologic pattern than the previous tachycardia beats. Additionally, local activation time, measured with respect to the onset of the QRS complex, of proximal and distal right ventricle during the last tachycardia beat was shorter than that of the previous tachycardia beats.

These findings reflect that after a gradual increase in retrograde slow AV nodal pathway conduction, a fast AV nodal pathway becomes capable of anterograde conduction, leading to anterograde His bundle activation. Because of the simultaneous activation of the ventricle by this AV nodal echo beat and the wavefront coming across the accessory pathway, fusion occurs on the ventricular level. Tachycardia is terminated and sinus rhythm restored.

Change of atrioventricular nodal pathway during antidromic tachycardia: In the 3 other patients (nos. 3, 4 and 5) with antidromic reciprocating tachycardia, retrograde conduction time (VA interval) during tachycardia averaged 220 ms. Tachycardia termination was always preceded by a sudden shortening of retrograde conduction time, indicated by a decrease of the VA interval to an average of 140 ms. This sudden decrease of retrograde AV nodal conduction time led to termination of reciprocating tachycardia either on the atrial level (2 patients; Fig. 2) or, after anterograde conduction through the accessory pathway, on the ventricular level (1 patient). Bundle branch reentry beats were not induced in these patients during atrial or during ventricular pacing.

The assumed mechanism for this type of reciprocating tachycardia termination is a change of retrograde conduction from a slowly conducting to a rapidly conducting AV nodal pathway, leading to either antero-

grade block in the accessory pathway or retrograde block in the His-Purkinje-AV node axis.

Intravenous application of atropine invariably enhanced fast retrograde AV nodal pathway conduction, resulting in 1:1 ventriculoatrial conduction through the fast AV nodal pathway during sustained tachycardia in all 3 patients. Ventricular premature beats delivered during tachycardia neither advanced atrial activity nor changed retrograde atrial activation sequence.

Atrioventricular nodal echo in orthodromic tachycardia: In the 2 patients with orthodromic reciprocating tachycardia (nos. 6 and 7), termination occurred after a sudden change from short tachycardia cycles to a long cycle. Intracardiac recordings revealed that the increase of tachycardia cycle length was due to an increase of anterograde AV nodal conduction time (AH interval), followed by simultaneous activation of atria and ventricles (Fig. 3). Cycle length prolongation was accompanied by a change of retrograde atrial activation sequence. During tachycardia, earliest atrial activation occurred in the distal coronary sinus, followed by proximal coronary sinus, His area and high right atrium, suggesting conduction across a left laterally localized accessory pathway. After cycle length prolongation and termination of tachycardia, earliest activity occurred in the low right atrium, followed almost simultaneously by activation of coronary sinus and high right atrium. This activation sequence suggests retrograde conduction through the AV node.

The increase in anterograde AV nodal conduction time and the change in timing and sequence of retrograde atrial activation after an increase in tachycardia cycle length presumably reflects a switch of anterograde AV conduction from a fast to a slow AV nodal pathway. During reciprocating tachycardia anterograde conduction predominantly occurs through the fast AV nodal pathway and retrograde conduction through the accessory pathway. Sudden conduction block in the fast pathway switches anterograde conduction to the slow AV nodal pathway, allowing the impulse to reinvade the atria not only through the accessory pathway but also through the fast AV nodal pathway (AV nodal echo beat). It is postulated that simultaneous retrograde activation through the accessory pathway and the AV node leads to collision of both wavefronts on the atrial level, thereby terminating tachycardia and restoring sinus rhythm.

Follow-up: During a follow-up period of 11 ± 4 months, none of our patients received antiarrhythmic treatment, and sustained episodes of tachycardia were never documented.

Discussion

Spontaneous termination of reciprocating tachycardia in the presence of accessory AV pathways occurs

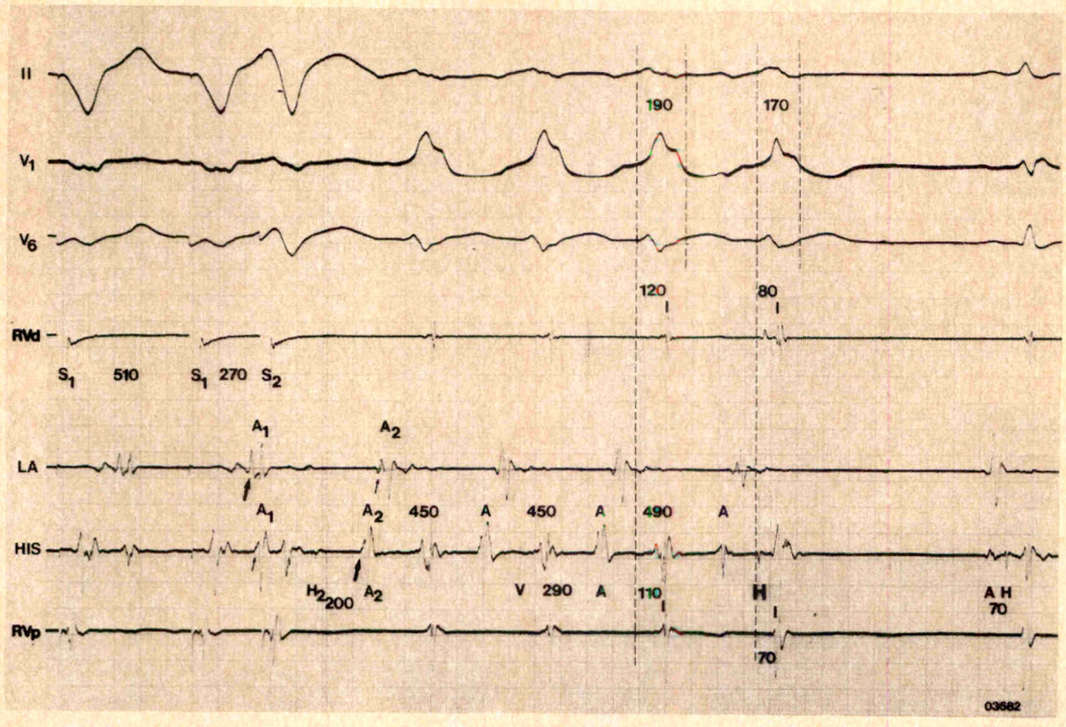

FIGURE 1. Patient 1. Delivery of a ventricular premature beat (S_2) after 270 ms during right ventricular pacing with a basic cycle length of 510 ms. **Arrows** mark retrograde atrial activation sequence (A_1), showing earliest activity during basic pacing (S_1S_1) in left atrium (LA) (**thick arrow**), followed by His bundle area (HIS, **thin arrow**), indicative of conduction through a left-sided accessory pathway. Following S_2, atrial activation (A_2) occurs after the appearence of a retrograde His potential (H_2A_2 200 ms). Earliest activation now occurs in HIS (**thick arrow**), followed by left atrium (**thin arrow**), indicative of conduction through the AV node. After conduction of A_2 to the ventricles, 4 tachycardia cycles with a wide QRS complex are initiated. Retrograde atrial activation sequence during tachycardia is the same as after S_2. After an increase in AA interval during tachycardia from 450 to 490 ms, a His potential (H) appears at the onset of the last tachycardia QRS complex. Note the difference in shape and width of this beat (170 ms), compared with the 3 previous beats (190 ms). Local activation times of distal (RVd) and proximal right ventricle (RVp), measured from the onsets of the QRS complexes (**dashed vertical lines**), shorten from 120 to 80 ms and from 110 to 70 ms, respectively. See text for explanation of the proposed mechanism.

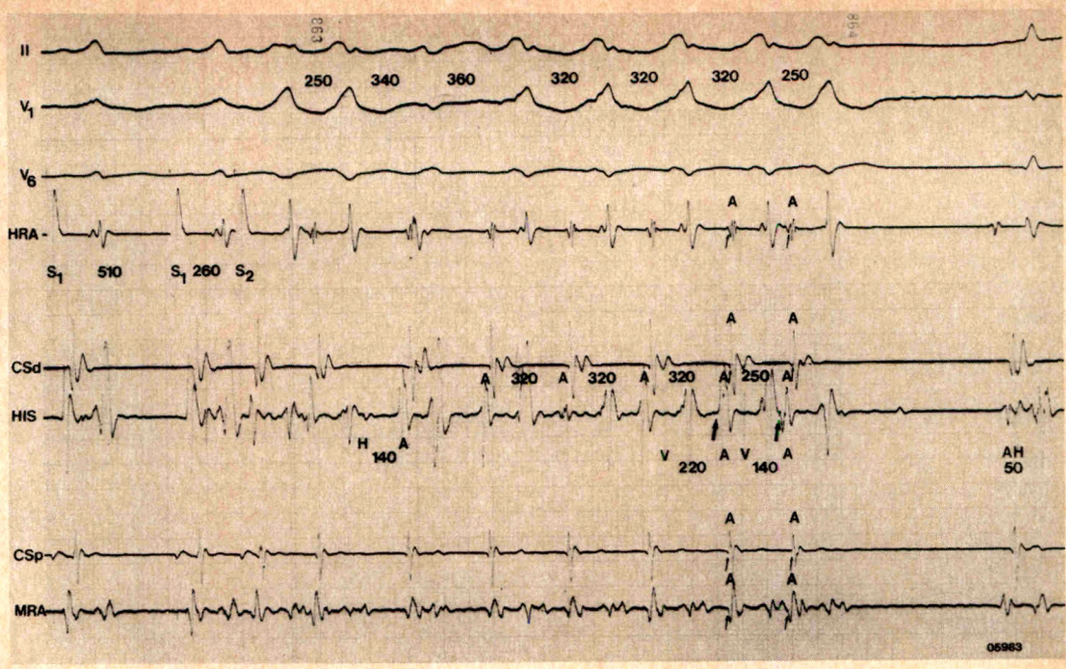

FIGURE 2. Patient 4. Delivery of a premature atrial beat (S_2) at 260 ms during right atrial pacing with a basic cycle length of 510 ms. S_2 initiates a tachycardia with a wide QRS complex. Retrograde atrial activation sequence during tachycardia revealed earliest activity in His bundle area (HIS) (**thick arrow**), followed by proximal coronary sinus (CSp), distal coronary sinus (CSd) and high right atrium (HRA) (**thin arrows**). After first tachycardia beat a retrograde His spike can be identified, suggesting retrograde conduction through the AV node. Note the spontaneous change of cycle length during tachycardia (250 to 360 ms) as a result of changes of VA interval. Tachycardia is antidromic. Sudden shortening of VA interval from 220 to 140 ms does not change retrograde atrial activation sequence (**arrows on right**) and anterograde conduction through the accessory pathway, but leads to retrograde block. See text for proposed mechanism. MRA = midright atrium.

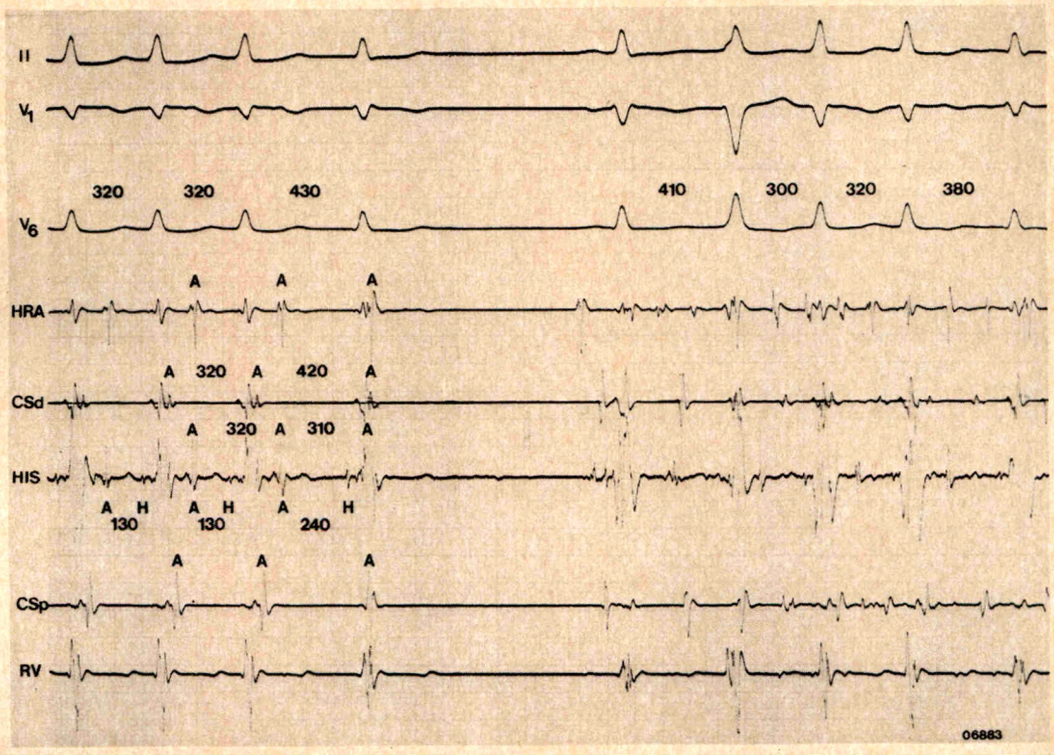

FIGURE 3. Patient 6. Spontaneous termination of orthodromic reciprocating tachycardia (cycle length 320 ms) after a sudden increase of cycle length to 430 ms. This cycle length prolongation is caused by an increase in the AH interval from 130 to 240 ms. Retrograde atrial activation sequence during tachycardia shows earliest activity in distal coronary sinus (CSd), followed by proximal coronary sinus (CSp), His bundle area (HIS) and high right atrium (HRA). After cycle length prolongation, earliest retrograde activation is observed in HIS, followed almost simultaneously by CSp, CSd and HRA. Note altered QRS morphologic pattern (s in II, r′ in V_1) in surface leads II and V_1 as a result of altered retrograde atrial activation. After termination of tachycardia, impure atrial flutter is spontaneously initiated. See text for proposed mechanism. RV = right ventricle.

in about 40% of patients undergoing electrophysiologic study.[12] Usually, the site of block is the accessory pathway or the AV node, but occasionally it is the His-Purkinje system. Several investigators have suggested the coexistence of dual AV nodal pathways and anomalous AV bypass tracts in patients. The electrophysiologic importance of this phenomenon was mainly seen in the coexistence of both AV nodal and AV reentrant tachycardia,[13,14] and in the inducibility and maintenance of these types of tachycardia.[5,6] The electrophysiologic demonstration of dual AV nodal pathways in the presence of an accessory AV connection included alternation of tachycardia cycle length and the recording of discontinuous AV nodal conduction curves.[4,5,15]

In this study we have shown that the presence of dual AV nodal pathways in patients with an accessory AV pathway may be diagnosed only indirectly, by the mode of spontaneous termination of reciprocating tachycardia. Although different modes of tachycardia termination were observed, the underlying mechanism was always a sudden switch between a slowly conducting and a rapidly conducting AV nodal pathway, either concomitant with intranodal reentry or not. It is not known why intranodal conduction changes from one pathway to another during reciprocating tachycardia. Changes of refractoriness after the onset of and during tachycardia or a fatigue phenomenon in one pathway may be the cause.

Instead of intranodal reentry, termination of tachycardia might also be caused by His extrasystoles. However, this mechanism appears to be unlikely because, in each patient, the time intervals leading to termination were identical in all episodes of tachycardia.

The possibility of a second accessory pathway responsible for the change in retrograde conduction during tachycardia must be considered. Exclusion of such a pathway is only possible by indirect criteria. After retrograde block had occurred in the proved accessory pathway, retrograde conduction to the atria was in all patients dependent on the S_1H_2 interval, never on the S_1S_2 (or V_1V_2) interval. The S_1H_2 (and consequently A_1A_2) intervals progressively prolonged with gradual shortening of S_1S_2. Retrograde atrial activation was always preceded by a His deflection before the onset of tachycardia. Furthermore, the retrograde atrial activation sequence was always in accordance with conduction through the AV node and it never changed, neither after the first tachycardia activation sequence nor during the following tachycardia beats. In 3 patients with sustained tachycardia after administration of atropine, delivery of ventricular premature beats during tachycardia never advanced atrial activity or changed retrograde atrial activation sequence. Finally, it appears highly unlikely that all patients had a second concealed accessory pathway which would have to be located septally with decremental conduction properties.

In 3 patients without an echo phenomenon, the lack of retrograde His potentials during antidromic tachycardia did not allow us to determine the mechanism of the sudden decrease of retrograde conduction time. Retrograde input into the AV node through different parts of the bundle branch system may cause cycle length variations in antidromic reciprocating tachycardia.[16] However, in our patients, no form of bundle branch reentry could be induced, neither during atrial nor during ventricular stimulation; moreover, atropine, which is known to have a greater influence on nodal than on subnodal tissue, changed the characteristics of the induced arrhythmia.[17]

The high percentage of antidromic reciprocating tachycardia found in our patients is unusual. We do not know whether patients with antidromic reciprocating tachycardia have electrophysiologically functioning dual AV nodal pathways more often than patients with orthodromic reciprocating tachycardia or whether the anterograde or retrograde conduction characteristics of the AV node are different in these patients.

The early spontaneous termination of reciprocating tachycardia in patients with an accessory pathway owing to interaction of dual AV nodal pathways, as proposed in this study, may indicate that these patients have clinically less symptomatic arrhythmias than patients without dual AV nodal pathways.

Electrophysiologic Evaluation of the Antiarrhythmic Effects of N-Acetylprocainamide for Ventricular Tachycardia Secondary to Coronary Artery Disease

JONATHAN WYNN, MD, DENNIS S. MIURA, MD, VILMA TORRES, MD, DAVID FLOWERS, MD, DEBORAH KEEFE, MD, SHARON WILLIAMS, PA, and JOHN C. SOMBERG, MD

Antiarrhythmic properties of N-acetylprocainamide (NAPA), an active metabolite of procainamide, were studied in 12 patients with coronary artery disease who presented with cardiac arrest or documented sustained ventricular tachycardia (VT). Programmed electrical stimulation (PES) studies were performed in 10 men and 2 women, aged 52 to 80 years (mean 63), who had a left ventricular ejection fraction of 16 to 69% (mean 33). All patients tested had inducible VT provoked by PES without antiarrhythmic therapy. Patients were then tested with procainamide, 1,000 mg administered intravenously. VT could be provoked after procainamide treatment in 8 of 10 patients. Twenty-four to 36 hours later NAPA was administered, 18 mg/kg body weight intravenously, and PES was performed after 20 minutes. NAPA did not significantly change heart rate, mean arterial blood pressure, electrocardiographic intervals and AH or HV conduction times. The QT interval lengthened, but not significantly. The mean serum NAPA levels were 15.7 ± 4 μg/ml in the group protected by NAPA and 16.2 ± 4 μg/ml in the group not protected by NAPA. Five patients were discharged with NAPA therapy, 1.5 g orally every 8 hours. Two patients have been maintained with chronic NAPA therapy (10 ± 3 months), and 2 patients had breakthrough VT on follow-up Holter monitoring and alternative therapy was given. One patient died while taking oral therapy. NAPA demonstrates antiarrhythmic efficacy in preventing induction of VT by PES in a high-risk group of patients. During chronic oral therapy in some patients, NAPA appears to be well tolerated, with antiarrhythmic efficacy that may be enhanced with further upward dose titration.

(Am J Cardiol 1985;56:877–881)

N-acetylprocainamide (NAPA), the N-acetylated metabolite of procainamide, has been shown to have antiarrhythmic properties in humans and in isolated tissue preparations.[1–4] Some studies reported that NAPA has antiarrhythmic properties similar to those of procainamide.[5–7] However, the electrophysiologic properties of NAPA in isolated Purkinje fiber preparations are different from those of its parent compound, procainamide, in that it neither suppresses automaticity because of phase 4 depolarization nor depresses action potential amplitude or maximal upstroke velocity.[8] NAPA apparently exerts its antiarrhythmic effects through prolongation of the action potential duration and the effective refractory period.[9,10] NAPA has an advantage over the parent compound by having a longer elimination half-life of approximately 10 hours,[11] and a substantially lower incidence of the drug-induced lupus-like syndrome.[12,13] Earlier clinical studies described antiarrhythmic properties of NAPA during chronic oral dosing in humans,[14–18] but did not deal with its efficacy in the electrophysiology laboratory during acute intravenous administration and programmed electrical stimulation (PES).

To determine the effectiveness of NAPA in preventing induction of ventricular tachycardia (VT) by PES, we studied patients who presented with cardiac arrest or a history of sustained VT. If NAPA was found to be effective at PES testing, patients were treated with NAPA to assess its efficacy during long-term therapy.

Methods

Twelve patients (10 men, 2 women) with a history of cardiac arrest and 2 with sustained VT were evaluated using electrophysiologic methods to determine antiarrhythmic therapy. All antiarrhythmic drugs, calcium antagonists and β blockers were discontinued for 5 half-lives before the initiation of the study. Therapy with nitrates and diuretic drugs was continued for the treatment of angina and symptoms of congestive heart

failure. Baseline electrocardiogram, chest x-ray, urinalysis, and hematologic and chemistry profiles were also obtained. Informed consent was obtained before each study. The consent form and protocol were approved by the Committee on Clinical Investigation at the Albert Einstein College of Medicine.

Drug infusion protocol: Baseline heart rate, blood pressure, PR interval, QRS, QT duration, sinus node recovery times, atrial-His and His-ventricular conduction times were recorded. The patients then received an intravenous infusion of NAPA at a dose of 18 mg/kg body weight over 20 minutes. Electrophysiologic evaluations were done at the end of 20 minutes of the infusion. All baseline variables were repeated and the patients then underwent serial drug testing with the PES protocol as outlined later.

During all PES studies, before and after drug administration, surface electrocardiographic leads I, II, aVF and V_5 were continuously monitored and printed on 8-channel paper using a Siemens Elema mingograph.

Chronic drug therapy: The patients who were protected with NAPA were then given oral therapy, 1.5 g every 8 hours. They were then followed up every month with monitoring of NAPA serum levels, hematologic and chemistry profiles, electrocardiography, urinalysis and Holter electrocardiographic monitoring.

Programmed electrical stimulation protocol: After the patients gave informed consent, PES was performed using a hexapolar catheter introduced transvenously in the apex of the right ventricle. For patients in whom VT could not be induced from the right ventricular apex, the catheter was repositioned in the right ventricular outflow tract. A digital stimulator (Bloom Associates) was used to deliver rectangular electrical impulses 2 ms in duration with amplitude set at twice diastolic threshold. The right ventricle was driven with a pacing train of 6 beats at a cycle length of 500 ms with an intertrain interval of 8 seconds.

Single premature ventricular stimuli (S_2) were introduced in late electrical diastole, starting at 500 ms from the end of the pacing train and progressively introduced earlier by 10 ms decrements. The shortest interval at which S_2 failed to evoke a depolarization was termed the effective refractory period. The stimulus was brought out 10 ms further from the first stimulus refractory period, and a second extra stimulus was introduced at 500 ms from this last stimulus. This programmed introduction of premature stimulus was performed until VT (more than 10 beats) was obtained or until 3 premature stimuli were introduced.

Nonsustained VT was defined as VT of more than 10 beats terminating spontaneously, and sustained VT was defined as VT lasting 30 seconds or requiring either pacing techniques or cardioversion to terminate the tachycardia. Patients who had VT provoked by 3 stimuli while not taking antiarrhythmic agents were evaluated by 4 stimuli while taking antiarrhythmic therapy. To be protected by a drug, 4 stimuli could not provoke VT in these patients.

Serum N-acetylprocainamide determination: Analysis of serum NAPA levels were performed by an independent drug laboratory at the clinical pharmacology section of the Northwestern University School of Medicine using a high-pressure liquid gas chromatographic technique with a sensitivity of 1 μg/ml.

Statistical analysis: Data are expressed as mean ± standard error of the mean. Differences between the means were determined by the Student t test and for multiple comparisons, an analysis of variance was used. A 2-tailed test was used to determine the level of significance. The JT interval was calculated as the QT interval minus the QRS duration. The percent change of the JT interval and the effective refractory period of the first extrastimulus (S_2) were compared using linear regression and a Z transform to determine significance.

Results

The study population consisted of 12 patients (10 men, 2 women) average age 63 ± 2 years (Table I). The presenting problem was a cardiac arrest in 10 patients (83%) and sustained VT in 2 (17%). Before electrophysiologic evaluation, the patients had poor clinical results with an average of 2 drugs (breakthrough VT or development of toxic side effects). The mean left ventricular ejection fraction for the patient group was 33 ± 6%. At the time electrophysiologic studies were performed, 1 patient was in New York Heart Association functional class I, 5 were in class II, 4 were in class III and 2 were in class IV.

Electrophysiologic studies: The PES studies were performed in patients whose antiarrhythmic medications were discontinued for at least 5 half-lives. All patients who were entered into the study had inducible VT by PES techniques (Fig. 1). Eight patients (67%) had nonsustained VT induced (12 to 30 seconds of VT), and 4 patients (33%) had sustained VT induced, which was terminated with direct current countershock in 2 patients (17%) and pacing techniques in 2 (17%). The mean rate of VT during the control run was 278 ± 9 beat/min. If nonsustained VT developed, we did not continue to provoke sustained VT but accepted the nonsustained VT as an index of electrical instability and proceeded to acute antiarrhythmic drug testing.

Results of drug testing: After intravenous infusion of NAPA, mean arterial blood pressure, heart rate, PR interval, QRS duration, QTc, AH and HV intervals did not change significantly. After NAPA was given, VT was no longer inducible in 5 patients (42%). VT was induced in 7 patients (58%) at a slower mean rate of 220 beats/min ($p < 0.05$) after administration of NAPA. The effective refractory period was prolonged significantly for the first extrastimulus, from 238 ± 5 to 291 ± 13 ms ($p < 0.01$). The mean serum NAPA level in the "protected" group was 15.7 ± 4 μg/ml and the mean NAPA level in the patients with inducible VT was 16.2 ± 4 μg/ml. Five of the 7 patients (71%) who were not protected at PES with NAPA required experimental agents to control their VT. The patients who were not protected by

TABLE II Effects of Intravenous N-Acetylprocainamide (NAPA) on Electrocardiographic Intervals and Ventricular Refractoriness in Relation to the Effects of the Drug on the Inducibility of Ventricular Tachycardia

	HR (beats/min)	PR (ms)	QRS (ms)	QTc (m)	ERP S_2* (ms)	ERP S_3† (ms)

Protected	84 ± 7	170 ± 9	108 ± 20	460 ± 22	298 ± 13‡	273 ± 21‡
Inducible	77 ± 5	188 ± 9	103 ± 9	467 ± 10	277 ± 10‡	278 ± 52‡

* ERP S_2 = effective refractory period of the first extra stimulus.
† ERP S_3 = effective refractory period of the second extra stimulus.
‡ ERP significantly different from control values ($p < 0.05$).
HR = heart rate.

NAPA were discharged taking the following agents: lorcainide (1 patient), amiodarone (2 patients) and quinidine, ethmozine, pirmenol and procainamide (1 patient each).

Three additional patients with a history of cardiac arrest and a cardiomyopathy without CAD were studied. All 3 had VT provokable without antiarrhythmic therapy; 1 was protected with NAPA, and is alive and well after 10 months of oral therapy.

The clinical electrophysiologic profile of NAPA did not show a prolongation in conduction as measured by the HV interval or the QRS duration (Table II). The ventricular refractory period was measured by the extrastimulus technique and repolarization was determined by measurement of the JT interval. The mean JT increased from 266 ± 12 to 297 ± 10 ms ($p < 0.05$). To determine the relative effects of NAPA on refractoriness and repolarization, the percent change from the drug-free state in refractoriness was plotted on the ordinate and the percent change in the JT interval plotted on the abscissa (Fig. 2). This relation was examined in patients that were protected at PES studies and those not protected by NAPA. A linear relation was found ($r = 0.95$) for the group in which NAPA prevented VT induction but not for the group in which NAPA had no effect on VT inducibility ($r = -0.26$). The 2 groups were significantly different ($p < 0.005$).

Procainamide and N-acetylprocainamide comparative results: Ten patients were tested in the electrophysiology laboratory with procainamide and NAPA. The other 3 patients had poor clinical results with procainamide; 2 had breakthrough VT and 1 patient showed toxic side effects. Eight of the 10 patients who were tested with procainamide had inducible VT at PES. The 2 patients found to be protected with procainamide had inducible VT with NAPA (Fig. 1).

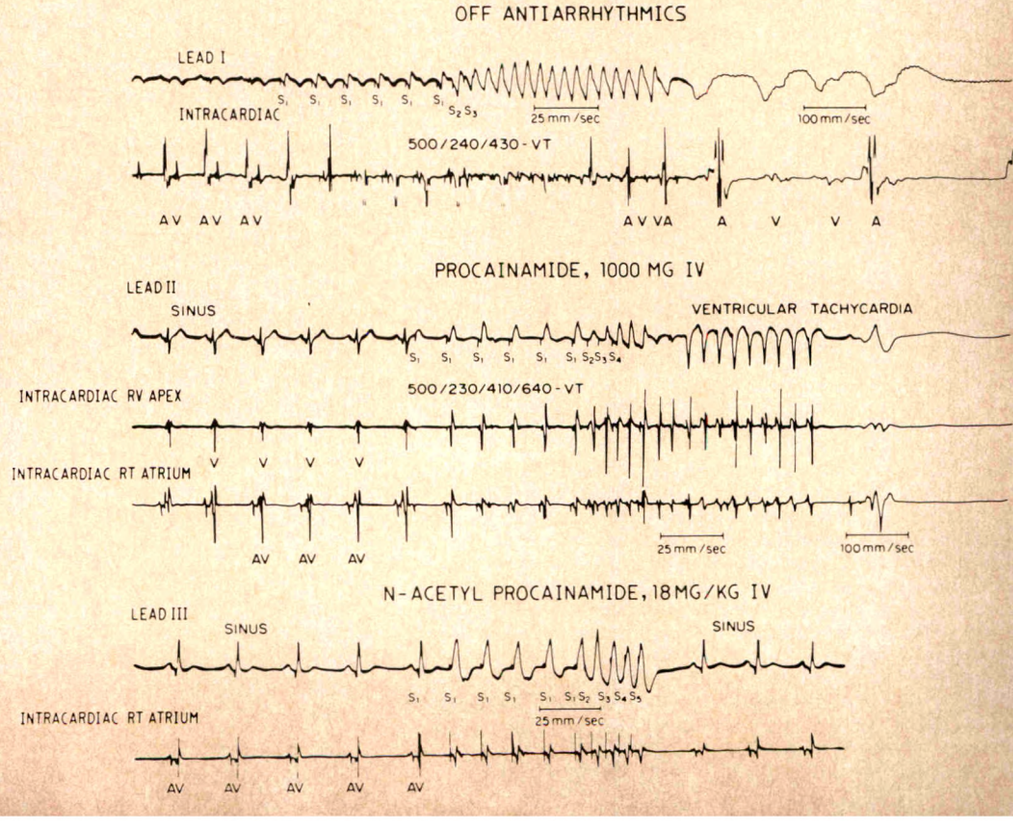

FIGURE 1. Differential effects of N-acetylprocainamide and procainamide on electrophysiologic testing. Electrophysiologic studies were initially performed without antiarrhythmic therapy with induction of ventricular tachycardia (VT) (**top**) followed by acute drug testing. Procainamide (1,000 mg administered intravenously (IV)) failed to prevent induction of VT (**middle**). After 30 hours of drug washout, N-acetylprocainamide was administered intravenously (18 mg/kg) and VT could not be induced at electrophysiologic testing (**bottom**) despite the introduction of 4 premature stimuli.

D.S.	ND	15	

* Concentration of procainamide when only NAPA was given (measurement of deacytalation).
† Patients with breakthrough arrhythmias.
ND = not detectable; PES = programmed electrical stimulation; tid = 3 times daily.

The mean procainamide level in the group protected with procainamide was 7.7 ± 1 μg/ml and the level in the nonprotected group was 9.2 ± 3 μg/ml (Table III). Six patients were protected with NAPA and 3 were tested with procainamide; in all 3, VT could be induced using PES techniques. There was no correlation between effective refractory period and JT interval for either the protected, nonprotected or combined groups receiving procainamide.

Long-term experience: Five patients (with coronary artery disease) were discharged from the hospital receiving oral NAPA. Three patients are doing well, with no VT on Holter monitoring, after 10 ± 3 months of follow-up. These patients have a mean NAPA level of 32 ± 12 μg/ml. One of 5 patients was discharged from the hospital by his primary physician before NAPA serum levels could be determined. The patient died 2 days later. The cause of death and compliance with the oral NAPA protocol remain unknown. Two of the remaining 5 patients who were taking NAPA had breakthrough nonsustained VT on Holter monitoring, NAPA therapy was discontinued. Antiarrhythmic efficacy may have been enhanced with further upward dose titration. The adverse effects with NAPA therapy were minor and included nausea and dizziness. These effects have diminished with continuation of drug therapy.

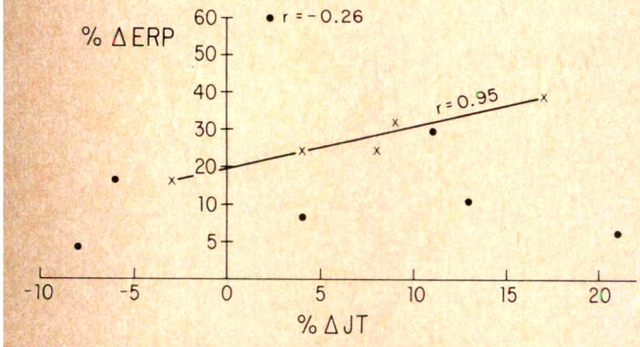

FIGURE 2. The correlation between changes in the JT interval (% ΔJT) and those in the effective refractory period (% ΔERP) relative to the effects of intravenous N-acetylprocainamide (NAPA) on the inducibility of ventricular tachycardia in patients with life-threatening ventricular tachyarrhythmias: The percent change in the JT interval after NAPA administration is calculated for each patient and plotted on the **abscissa** while the percent change in the effective refractory period (ERP S_2) after NAPA is plotted on the **ordinate.** In the group protected by NAPA (x—x), a linear correlation is seen between changes in JT and ERP (r = 0.95), whereas in the group in which ventricular tachycardia could still be induced (●), no correlation was seen between the changes in ERP and JT (r = −0.26). The relation of ERP and JT in the protected group are significantly different from that in the group in whom ventricular tachycardia could still be provoked ($p < 0.005$) after NAPA administration.

Discussion

PES techniques in our laboratory found NAPA to be an effective antiarrhythmic agent in a drug-resistant group. This group was at high risk of sudden death owing to ventricular tachyarrhythmias in the setting of impaired ventricular function; only 2 of the 12 had responded to procainamide therapy. Thus, this group could be considered a drug-resistant population, and the 40% efficacy of intravenous NAPA is impressive.

NAPA appeared to have an effect on the measured clinical electrophysiologic variables as might be expected from the results of cellular electrophysiologic studies.[8–10] Unlike the membrane-active "quinidine-like" or class Ia agents, NAPA did not prolong the QRS duration or the His-Purkinje conduction time as measured by the HV interval. NAPA did, however significantly prolong the JT interval, a measure of repolarization and voltage-dependent myocardial refractoriness determined by the extrastimulus technique. A comparison of the change in JT interval and effective refractory period S_2 showed a linear correlation for the protected group, but not for the nonprotected group. This correlation of JT interval and effective refractory period may represent an insight into the antiarrhythmic mechanism of NAPA and, possibly, other type III agents. In fact, studies in humans and dogs with bepridil, a calcium-blocking agent that prolongs the QT

interval, showed a similar relation, whereas quinidine failed to show this type of relation.[19,20] Prolonging repolarization may increase myocardial electrical homogeneity so that a stimulus causing focal reexcitation falls on a myocardium uniformly still refractory to stimulation. The heterogeneity of myocardial refractoriness caused by ischemic heart disease or myopathy may set the stage for a reentrant tachycardia. A nonuniform prolongation in repolarization may favor the development of ventricular tachyarrhythmias.[21] Uniform prolongation of repolarization would prolong refractoriness and may thus prevent reentrant tachycardias. The current study suggests that when refractoriness and repolarization are effected in concert, NAPA is effective in preventing VT induction.

Our results with chronic oral therapy show the need for oral dose titration. In 1 patient, (who died suddenly and had been in New York Heart Association functional class IV), we could not provide predischarge counseling with respect to drug dosage or determine the adequacy of therapeutic NAPA levels. The 2 other patients with nonsustained VT on Holter monitoring, in retrospect, had NAPA levels that may have permitted higher drug dosages to be administered. One patient with VT had an NAPA level during chronic therapy slightly lower than that after intravenous drug administration, preventing VT induction; the other patient with breakthrough VT had a NAPA level slightly higher than that found at the PES study. Whether a direct relation exists between the effects of intravenous NAPA preventing VT induction and long-term clinical outcome with chronic drug therapy, could not be established in the present study because of the limited study population. The results do suggest promise and indicate the need for further study using higher oral NAPA doses with correspondingly higher chronic serum concentrations.

Atkinson et al[17] found that oral NAPA causes a significant reduction in frequency of ventricular premature complexes (VPCs) in 9 of 10 patients, with 1 patient showing an increase in frequency of ectopic rhythm. Long-term follow-up of these patients shows a 70% reduction in mean VPC frequency. Also, when the NAPA levels were subtherapeutic, there was an increase in VPC frequency. Kluger et al[14,16] found that NAPA was effective, with acute intravenous administration causing a 70% reduction in VPCs. However, over a 12-month period, 8 of 20 patients withdrew from the study because of recurrent arrhythmias or death. Only 6 of the initial 29 patients had a persistent 70% reduction in VPC frequency. NAPA levels were not reported in the chronic phase of this study, and it is not clear if the patients with breakthrough arrhythmias had subtherapeutic or elevated levels of NAPA. Winkle et al[15] studied 11 patients receiving oral therapy and found that only 2 could achieve a 90% reduction in VPC frequency with NAPA. Lowering the criteria of drug efficacy to a 70% reduction in VPC frequency did not alter these findings. Our data in patients with life-threatening arrhythmias suggest that NAPA is effective in preventing VT induction at acute drug testing and may prevent spontaneous arrhythmias in selected patients.

NAPA has several potential advantages over procainamide in terms of adverse effects. Unlike the parent compound, procainamide, NAPA is not prone to induce the lupus syndrome or other immunologically mediated adverse effects.[20] In addition, NAPA has been reported to either augment contractility[23] or to have no significant depressant effect on cardiac function in patients undergoing diagnostic catheterization for ischemic heart disease (Josephson MA and Singh BN, personal communication). This finding is in contrast to the negative inotropic action of most antiarrhythmic agents.

NAPA appears to possess a low adverse reaction profile and to be effective in preventing VT induction at acute drug testing using PES techniques. Chronic oral administration of NAPA must be followed with serum level determinations and Holter monitoring. Increased oral dosing may be indicated because the effective chronic NAPA levels appear to be higher than previously believed and better tolerated.

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work may also be submitted.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript, including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article; (3) miniabstract for Table of Contents that includes the full title and names of all authors; (4) abstract; (5) text; (6) references; (7) acknowledgment; (8) figure legends; and (9) tables. Number all pages in the above sequence, beginning with the title page as 1, the abstract as 2, and so on. (Leave the second title page and the miniabstract unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references), with at least 25-mm (1-inch) margins.

The second title page, on which the names and institution of the authors are omitted, gives the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is always honored.

TITLE PAGE, TABLE OF CONTENTS ABSTRACT AND MINIABSTRACT: For the **complete title page,** include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code.

Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 4 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage.

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

FIGURES: Submit 3 glossy, unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present," a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no."

BRIEF REPORTS: Brief Reports must be limited to no more than 3 text pages and 6 references. Longer ones usually will be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used in the body of the Brief Report.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor-in-Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

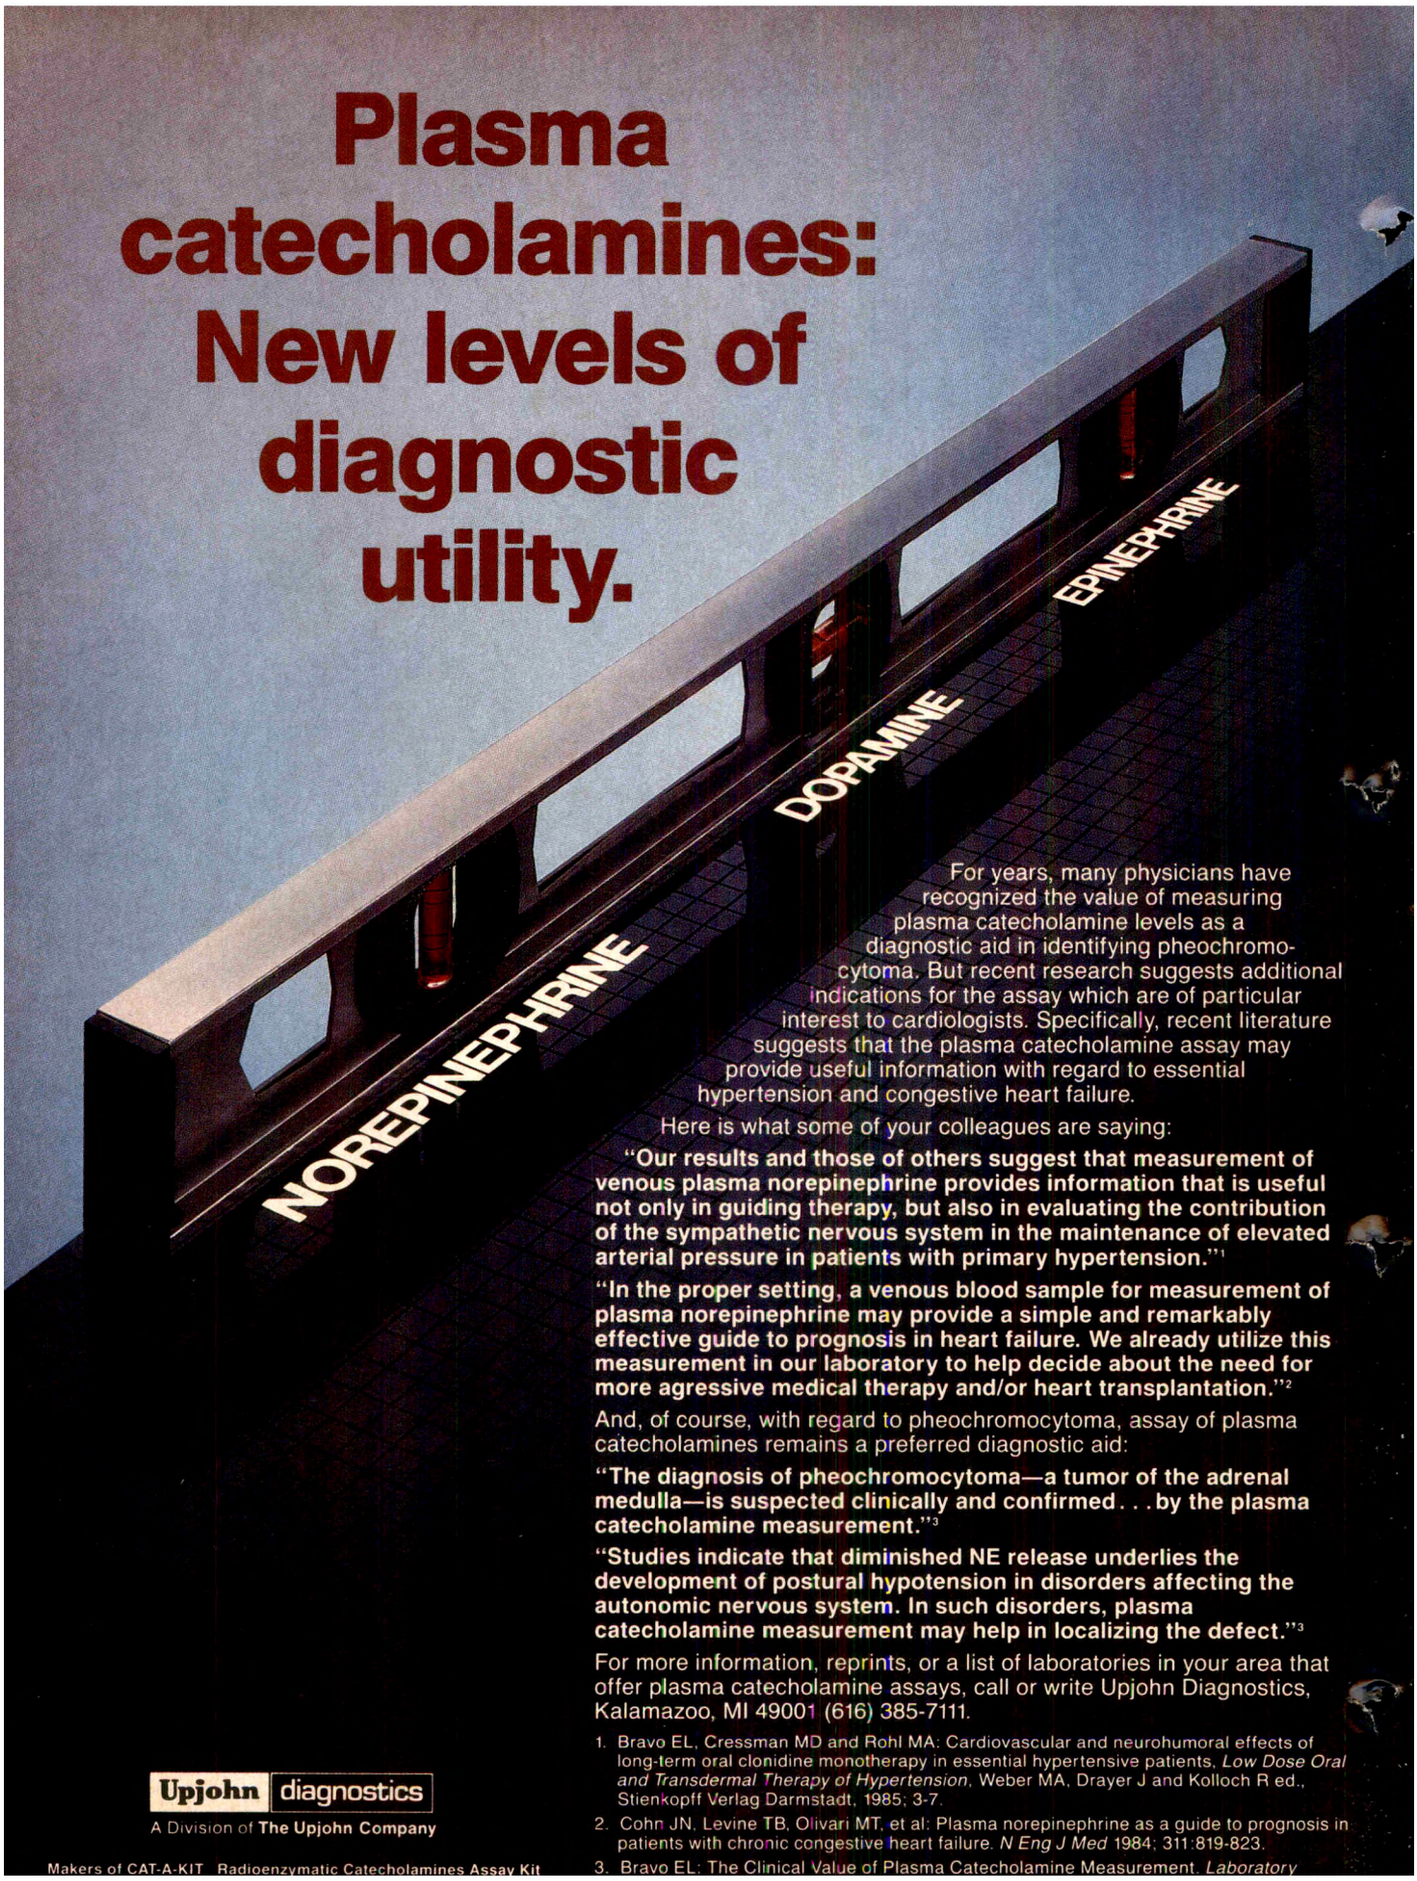
Plasma catecholamines: New levels of diagnostic utility.



For years, many physicians have recognized the value of measuring plasma catecholamine levels as a diagnostic aid in identifying pheochromocytoma. But recent research suggests additional indications for the assay which are of particular interest to cardiologists. Specifically, recent literature suggests that the plasma catecholamine assay may provide useful information with regard to essential hypertension and congestive heart failure.

Here is what some of your colleagues are saying:

"Our results and those of others suggest that measurement of venous plasma norepinephrine provides information that is useful not only in guiding therapy, but also in evaluating the contribution of the sympathetic nervous system in the maintenance of elevated arterial pressure in patients with primary hypertension."[1]

"In the proper setting, a venous blood sample for measurement of plasma norepinephrine may provide a simple and remarkably effective guide to prognosis in heart failure. We already utilize this measurement in our laboratory to help decide about the need for more agressive medical therapy and/or heart transplantation."[2]

And, of course, with regard to pheochromocytoma, assay of plasma catecholamines remains a preferred diagnostic aid:

"The diagnosis of pheochromocytoma—a tumor of the adrenal medulla—is suspected clinically and confirmed . . . by the plasma catecholamine measurement."[3]

"Studies indicate that diminished NE release underlies the development of postural hypotension in disorders affecting the autonomic nervous system. In such disorders, plasma catecholamine measurement may help in localizing the defect."[3]

For more information, reprints, or a list of laboratories in your area that offer plasma catecholamine assays, call or write Upjohn Diagnostics, Kalamazoo, MI 49001 (616) 385-7111.

Electropharmacologic Testing in Sustained Ventricular Tachycardia Associated with Coronary Heart Disease: Value of the Response to Intravenous Procainamide in Predicting the Response to Oral Procainamide and Oral Quinidine Treatment

DANIEL S. OSERAN, MD, ELI S. GANG, MD, MARK E. ROSENTHAL, MD, WILLIAM J. MANDEL, MD, and THOMAS PETER, MD

Twenty patients with inducible, sustained ventricular tachycardia (VT) were prospectively evaluated to determine whether the response to intravenous procainamide administration, as assessed by programmed ventricular stimulation, predicted the response to oral procainamide and oral quinidine treatment. Six patients (30%) responded to intravenous procainamide (fewer than 10 beats of inducible VT). Ten of 20 patients (50%) responded to oral quinidine and 5 (25%) responded to oral procainamide. Mean drug serum levels were 11.3 ± 2.1 μg/ml for intravenous procainamide, 5.4 ± 0.8 μg/ml for oral quinidine and 11.7 ± 3.4 μg/ml for oral procainamide. There was no significant difference in serum levels between those who responded and those who did not. Fifteen patients (75%) had a concordant drug response for intravenous and oral procainamide. Ten patients (50%) had a concordant response for intravenous procainamide and oral quinidine. Fifteen patients (75%) had a concordant drug response for oral procainamide and oral quinidine. Thus, in patients with sustained VT, the response to intravenous procainamide does not reliably predict the response to oral quinidine or oral procainamide, and serial day drug testing with these agents is necessary. Furthermore, high-dose quinidine therapy may be more effective in controlling VT in these patients than procainamide.

(Am J Cardiol 1985;56:883–886)

Serial electrophysiologic testing has been proposed as a means of selecting effective antiarrhythmic drug therapy in patients with ventricular tachycardia (VT).[1–4] This approach is based on the premise that the acute or subacute response to antiarrhythmic agents, as assessed by programmed ventricular stimulation, is predictive of the long-term clinical response to that agent. Some investigators suggest that the response to intravenous procainamide at the time of initial testing is predictive of the response to other antiarrhythmic agents.[5–7] The purpose of this study was to determine, in a prospective fashion, if the response to intravenous procainamide at the time of electrophysiologic study predicted the subsequent response to oral procainamide and oral quinidine in patients with sustained VT.

From the Department of Medicine, Division of Cardiology, Cedars-Sinai Medical Center, Los Angeles, California. Manuscript received February 5, 1985; revised manuscript received May 24, 1985, accepted May 28, 1985.

Methods

Patients: The study group consisted of 20 patients (17 men, 3 women), aged 30 to 77 years. All 20 patients had coronary heart disease.

All patients had inducible sustained VT at the time of electrophysiologic study. The referring diagnosis was recurrent sustained VT in 7 patients, sudden cardiac death in 7, and unexplained syncope in 6. Patients with a history of an adverse reaction to procainamide or quinidine were excluded. Three other patients could not complete the study because of side effects from quinidine treatment.

Electrophysiologic study protocol: Studies were performed in the postabsorptive state after the patient gave informed consent. All antiarrhythmic agents had been stopped for at least 5 half-lives before testing. Electrode catheters were inserted percutaneously and were positioned under fluoroscopic guidance in the high right atrium, right ventricular apex and His bundle position. Intracardiac recordings were filtered at 30 to 500 Hz and displayed simultaneously with 3 surface electrocardiographic leads (I, aVF and V_1) on a multichannel oscilloscope (Electronics for Medicine, VR-12). Stimulation was performed using a programmable stimulator (Bloom Associates) that delivered rectangular impulses 2 ms in duration. Programmed ventricular stimulation included the introduction of 1, 2 and 3 ventricular extrastimuli from

NAPA = N-acetylprocainamide; NI = no inducible ventricular tachycardia; PA = procainamide; PVS = programmed ventricular stimulation; Q = quinidine; SD = standard deviation; VT-NS = nonsustained ventricular tachycardia; VT-S = sustained VT.

2 right ventricular sites, at 2 paced cycle lengths, at 2 and 5 times diastolic threshold. Rapid ventricular burst pacing was also performed for 8 to 10 beats at cycle lengths of 60 to 250 ms in 50-ms decrements. The endpoint of stimulation was the induction of sustained ventricular arrhythmias (see definitions) or ventricular refractoriness.

Intravenous procainamide: After documentation of reproducibly inducible sustained VT, all patients received intravenous procainamide in a dose of 10 to 15 mg/kg at a rate of 30 to 50 mg/min. The mean dose of procainamide administered was 1,290 ± 300 mg (range 850 to 1,800). After the infusion was completed, repeat ventricular stimulation was performed using the protocol described herein. Again, stimulation was continued until VT was induced or ventricular refractoriness was reached. When the study was completed a serum sample was taken to measure procainamide and N-acetylprocainamide levels using a fluorescein polarization immunoassay.[8]

Oral procainamide and oral quinidine: After completion of the initial study, patients were randomly assigned to receive either oral procainamide or oral quinidine sulfate treatment with repeat ventricular stimulation after achieving therapeutic serum levels. All patients received both drugs in a sequential manner. The mean procainamide dose was 6.4 ± 1.7 g/day (range 3.0 to 9.0). The mean quinidine dose was 2.8 ± 0.4 g/day (range 2.4 to 3.6). Both drugs were administered for 48 to 96 hours, at which time repeat programmed ventricular stimulation was performed using the same stimulation protocol that was used in the initial study. Serum samples were obtained before programmed ventricular stimulation to document therapeutic levels, and at the completion of each study, for procainamide and quinidine levels, respectively, using a fluorescein polarization immunoassay.[8]

Definitions: *Sustained VT*—VT more than 30 seconds in duration or that required termination because of hemodynamic collapse. *Nonsustained VT*—VT longer than 6 beats that terminated spontaneously within 30 seconds. *Inducible VT*—VT induced at least twice during programmed ventricular stimulation. *Positive drug response*—inability to induce more than 10 beats of VT after administration of procainamide or quinidine.[9] *Negative drug response*—ability to induce more than 10 beats of VT after administration of procainamide.

Statistics: Statistical analysis was performed using Fisher's exact test, and Students *t* test for paired and unpaired data. A p value <0.05 was considered statistically significant.

Results

Response to antiarrhythmic agents: The results of programmed ventricular stimulation after drug administration are summarized in Table I. Six of 20 patients (30%) had a positive drug response (i.e., induction of less than 10 beats of VT) after administration of intravenous procainamide. Three other patients had inducible nonsustained VT longer than 10 beats. Eleven patients (55%) continued to have inducible sustained VT after intravenous procainamide. Five patients (25%) had a positive drug response to oral procainamide. Three patients had inducible nonsustained VT longer than 10 beats, whereas 12 patients (60%) continued to have inducible sustained VT.

Ten patients (50%) had a positive drug response to oral quinidine. Ten patients (50%) continued to have inducible sustained VT after oral quinidine therapy.

Antiarrhythmic drug concentrations: The mean procainamide concentration after the administration of intravenous procainamide was 11.3 ± 2.1 μg/ml, and 11.7 + 3.5 μg/dl after oral therapy. The mean quinidine concentration after the oral administration of quinidine was 5.4 ± 0.8 μg/ml. The mean procainamide concentration after intravenous procainamide was 10.7 ± 1.7 μg/ml in patients with a positive drug response and 11.5 ± 2.2 μg/ml in patients with a negative drug response (difference not significant [NS]). The mean procainamide level after oral administration of the drug was 12.5 ± 3.7 μg/ml in patients with a positive drug response and 11.1 ± 3.4 μg/ml in patients with a negative

drug response (NS). The mean quinidine concentration after oral quinidine therapy was 5.4 ± 0.7 μg/ml in patients with a positive drug response and 5.4 ± 1.0 μg/ml in patients with a negative drug response (NS).

Concordance of drug response: Figure 1 illustrates the concordance of drug response as assessed by programmed ventricular stimulation. Of the 6 patients with a positive drug response to intravenous procainamide, 3 had a positive drug response to oral procainamide and 3 had a negative response. Of the 14 patients with a negative drug response to intravenous procainamide, 2 had a positive response to oral procainamide and 12 had a negative response. Thus, 15 patients (75%) had a concordant drug response for intravenous and oral procainamide and 5 (25%) had a discordant response. Of the 6 patients with a positive drug response to intravenous procainamide, 3 had a positive response to oral quinidine and 3 had a negative response. Seven of the 14 patients with a negative drug response to intravenous procainamide had a positive response to oral quinidine and 7 had a negative response. Thus, 10 patients (50%) had a concordant drug response for intravenous procainamide and oral quinidine. Of the 5 patients with a positive drug response to oral procainamide, all 5 had a positive response to oral quinidine. Of the 15 patients with a negative drug response to oral procainamide, 5 had a positive response to oral quinidine and 10 had a negative response. Thus, 15 patients (75%) had a concordant drug response for oral procainamide and oral quinidine and 5 patients (25%) had a discordant drug response.

Discussion

We have evaluated the ability of intravenous procainamide to predict the efficacy of both oral procainamide and oral quinidine in the treatment of patients with sustained VT. The efficacy of intravenous and oral procainamide was 30% and 25%, respectively. This rate of positive drug response with procainamide is similar to that reported by other investigators.[10,11] The mean serum procainamide levels were 11 to 12 μg/ml and represent realistic target serum levels for such patients.

The rate of positive drug response after oral quinidine therapy was 50%. Previous studies have reported a rate of drug efficacy for quinidine of 24 to 34% in the treatment of patients with VT.[3,12,13] This greater degree of success achieved with quinidine in our study may, in part, be a result of the higher serum levels achieved. The mean serum quinidine level in this study was 5.4 ± 0.8 μg/ml. DiMarco et al[13] reported a 34% success rate in preventing the inducibility of VT using quinidine with a mean serum level of 2.9 ± 0.8 μg/ml. The substantially higher serum levels of quinidine in our study were achieved without a high incidence of untoward side effects. The assay used in this study is comparable in accuracy to that of other techniques.[14] This assay measures a total serum quinidine level, including metabolites such as dihydroquinidine. High-dose quinidine therapy in these patients, with target serum levels of 4 to 6 μg/ml, may result in a greater degree of drug efficacy than more standard dosages, in a fashion analogous to that of Greenspan et al,[11] with respect to high-dose procainamide therapy.

We found a 75% concordance in drug response between intravenous and oral procainamide. Marchlinski et al[10] found a 100% degree of concordance between intravenous and oral procainamide when comparable serum concentrations (within 3 μg/ml) were achieved. Four of the 5 patients in our study with a discordant response had comparable serum levels (within 3 μg/ml) after intravenous and oral therapy. Differences in stimulation protocols, definition of drug efficacy, and patient population between this study and that of

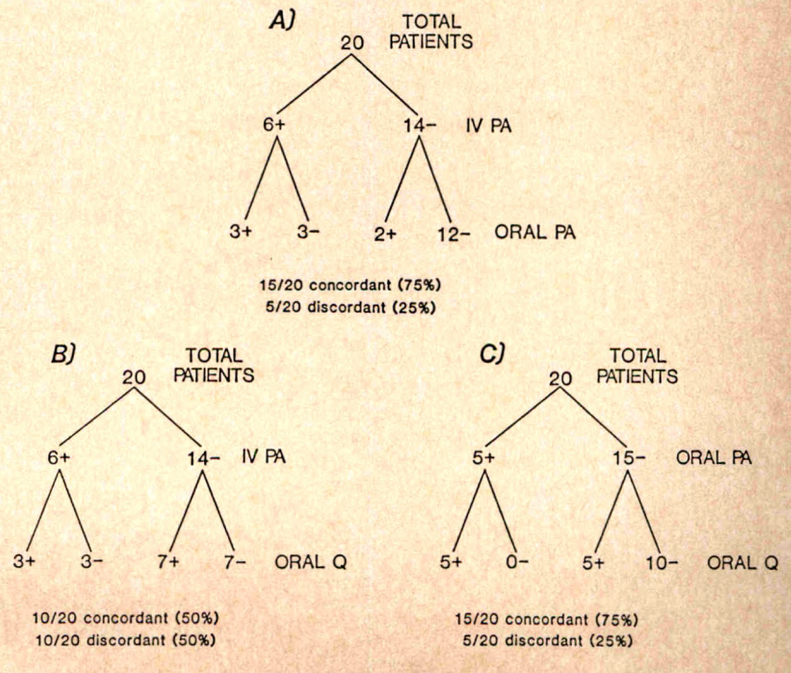

FIGURE 1. Effects of intravenous (IV) procainamide (PA), oral PA and oral quinidine (Q) on inducible ventricular tachycardia (VT) in 20 patients. **A**, intravenous PA compared with oral PA. **B**, intravenous PA compared with oral Q. + = positive drug response, defined as fewer than 10 beats of induced VT; − = negative drug response, defined as more than 10 beats of induced VT.

Marchlinski et al may contribute to differences in results.

A greater degree of discordance was found when comparing the drug responses to intravenous procainamide and oral quinidine treatment. There was a 50% rate of discordance between these 2 agents. Seven of 14 patients who failed to respond to intravenous procainamide had a positive drug response to quinidine. Waxman et al[12] reported only 2 of 42 successful drug trials with quinidine in patients whom intravenous procainamide had failed to prevent inducibility. Again, differences in serum levels may account for these findings. The mean serum quinidine level in the study by Waxman et al was 4.2 ± 1.3 μg/ml in patients with inducible VT and 3.5 ± 1.7 μg/ml in patients without inducible VT. In our study the mean serum quinidine level was 5.4 ± 0.7 μg/ml in patients with a positive drug response and $5.4 + 1.0$ μg/ml in patients with a negative drug response. The higher and more uniform serum quinidine levels in our study patients may explain our higher success rate using quinidine to abolish inducible VT.

Recently, other studies of the inability of procainamide to predict success with other antiarrhythmic drugs have been reported. Rae et al[15] found that 17% of patients with sustained VT and a negative drug response to procainamide went on to have successful prevention of VT induction with other antiarrhythmic drugs. In patients with ventricular fibrillation or nonsustained VT, this rate of success, despite procainamide failure, was 47% and 58%, respectively. Fogoros and Fiedler[16] found a 26% discordance between procainamide and other standard antiarrhythmic drugs in patients with inducible VT or fibrillation, with the bulk of the discordance owing to the efficacy of phenytoin. In our study much of the discordance was a result of the success of quinidine therapy.

Acute drug testing with intravenous antiarrhythmic drugs in patients with VT, may give misleading results with respect to the efficacy of oral agents. The presence of active metabolites that accumulate during oral therapy as well as myocardial concentration of drug during chronic oral therapy may all contribute to differences in drug effects between intravenous and oral therapy.[17–19] The ability to extrapolate or predict the efficacy of oral therapy from the response to acute intravenous administration of a drug is hampered by these factors, whether comparing 2 forms of the same drug or 2 different drugs in the same class. In the current study a 25% discordance of drug response was found between intravenous and oral procainamide and a 50% discordance between intravenous procainamide and oral quinidine. Moreover, our data suggest the importance and efficacy of high-dose quinidine therapy in the management of patients with sustained VT.

Spectrum of Antiarrhythmic Response to Encainide

HENRY J. DUFF, MD, DAN M. RODEN, MD, EDMUND L. CAREY, MD, THEODORE WANG, MD, R. KIRBY PRIMM, MD, and RAYMOND L. WOOSLEY, MD, PhD

Encainide is effective in suppressing non-life-threatening ventricular arrhythmias; however, inconsistent results have been noted in patients with more serious ventricular arrhythmias. Thirty-seven patients with drug-resistant ventricular arrhythmias were studied. Patients in group I (n = 11) had sustained ventricular tachycardia and those in group II (n = 26) had nonsustained ventricular arrhythmias. In group I, 8 patients had remote myocardial infarction, congestive heart failure and sustained ventricular tachycardia requiring repeated cardioversion (group Ia). None of these patients responded to encainide treatment, but 6 did have an antiarrhythmic response (complete in 3 and only partial in 3) to other investigational antiarrhythmic agents. Three patients in group I, all without ischemic heart disease (group Ib), had an excellent antiarrhythmic response to encainide, as did 21 of 26 patients in group II. In 4 of 5 patients in group II who did not respond, the dosage was limited due to the development of sinus pauses, atrioventricular block or bundle branch block, and in 3 of these 4 patients preexisting conduction disease was evident (PR longer than 0.2 second or QRS longer than 0.12 second). Diplopia occurred while taking the maximal oral dosage in the fifth patient. At 21.5 months of follow-up, 14 of the original 24 patients who responded to encainide continue to receive it; 3 have died (all due to natural progression of left ventricular dysfunction) and encainide was discontinued in 7: in 2 because of syncope, in 2 because of new-onset atrial fibrillation, in 1 patient because of exercise-induced polymorphic ventricular tachycardia, in 1 because of diplopia and in 1 because of skin exanthem.

Paradoxical worsening of ventricular arrhythmias occurred more frequently ($p < 0.01$) in patients in group Ia (4 of 8 patients) than in those in group Ib and II (3 of 29 patients). Although no significant relation could be established, paradoxical responses tended to be associated with higher encainide concentrations and greater prolongation of the QRS interval.

(Am J Cardiol 1985;56:887–891)

Encainide is an investigational drug that is effective in suppressing ventricular premature complexes (VPCs) and nonsustained ventricular tachycardia.[1–5] However, inconsistent efficacy has been noted in the treatment of more malignant ventricular arrhythmias. Mason et al[6] reported their experience in the treatment of 38 patients with recurrent, drug-resistant ventricular tachycardia and concluded that encainide was safe, well tolerated and often effective. However, we[7] and others[8,9] have noted paradoxical worsening of ventricular arrhythmias (both spontaneous and those induced by programmed electrical stimulation) during encainide treatment. Likewise, Winkle et al[9] noted that patients with malignant ventricular arrhythmias have the highest incidence of these paradoxical events. These discrepancies may be expected when any agent is used to treat ventricular arrhythmias of widely differing clinical severity, associated cardiac pathologic characteristics and mechanism. An understanding of the characteristics of patients least likely to respond to encainide and, more important, those with a greater risk for adverse effects would allow more effective selection of patients for treatment. We present our experience in 37 patients with drug-resistant ventricular arrhythmias.

Methods

Thirty-seven patients with high-frequency, complex and symptomatic ventricular arrhythmias who were nonresponsive or intolerant to conventional antiarrhythmic agents were included in this study. Conventional antiarrhythmic agents were considered ineffective if (1) computerized analysis of 12 to 24 hours of electrocardiographic data documented lack of sustained arrhythmia suppression (defined as less than 30% of baseline) or persistence of symptomatic arrhythmias when plasma drug concentrations were in the range usually associated with efficacy; (2) ventricular tachycardia (3 or more

AV = atrioventricular; LV = left ventricular; NYHA = New York Heart Association; VPCs = ventricular premature complexes; VT = ventricular tachycardia.

consecutive VPCs at a cycle length of less than 600 ms) persisted on a maximal, well tolerated dosage during ambulatory monitoring; (3) intolerable side effects or allergy developed that necessitated the discontinuation of therapy; or (4) therapy with a given agent was contraindicated. All patients had received antiarrhythmic therapy with quinidine, procainamide, propranolol and disopyramide (unless such therapy was contraindicated) without satisfactory response. VPC and ventricular tachycardia frequency were quantitated at baseline (24 to 48 hours of data at least 4 elimination half-lives after discontinuation of all previous antiarrhythmic therapy, if possible) and during therapy with gradually increasing dosages of encainide. The QRS duration was monitored at baseline and while encainide dosages were gradually increased. The endpoints of therapy were efficacy, paradoxical worsening of ventricular arrhythmia frequency or other manifestation of toxicity. Encainide was initially administered either intravenously or orally. Because antiarrhythmic efficacy had previously been observed over a wide range of dosages[1,2] and because details of an effective encainide infusion were not available at that time, each infusion was individually designed using the principles outlined herein (gradually increasing dosages of encainide, exploring the dose-response relations). The intravenous infusions of encainide (provided by Mead Johnson Pharmaceuticals) were given at 1 to 2 mg/min over 1 to 2 hours (from 50 to 240 mg), and this infusion rate was continued until efficacy or side effects occurred. If a patient responded to intravenous encainide, the infusion was discontinued and replaced with gradually increasing oral dosages of encainide (supplied as 25- and 50-mg tablets). If patients did not respond to intravenous encainide, the oral preparation was not assessed. Encainide therapy did not always begin with intravenous treatment; many patients received gradually increasing dosages of oral medication (with the same endpoints). The oral dosage schedule was to give encainide every 6 hours and dosage increments were considered only after 48 hours on a stable dosage (beginning at 12.5 mg to a maximum of 125 mg every 6 hours) in all patients with nonsustained ventricular arrhythmias (group II). However, in patients with sustained ventricular tachycardia with ischemic heart disease (group Ia), the schedule was individualized based on clinical urgency. Even so, the dosage schedule was every 6 hours in 5 of 8 patients in group Ia. In 3 patients in group Ia, encainide was given every 3 to 4 hours, for several dosages. Dosages were increased every 12 to 18 hours in patients in group Ia.

Arrhythmia frequency: Arrhythmia frequency was quantified using a Hewlett Packard computerized arrhythmia analysis system (HP 78220) located in the coronary care unit, or the electrocardiographic data were recorded on 8-track FM magnetic tapes using a Honeywell Model 96 FM recorder. Tapes were then analyzed by a computer operator using a PDP 11/60 laboratory minicomputer and a previously described and validated system.[10] This system records the number of VPCs and episodes of ventricular tachycardia using a template matching algorithm. Sustained ventricular tachycardia in this study is defined as more than 100 consecutive VPCs at a cycle length of less than 600 ms.

Electrophysiologic studies: Eleven patients were studied using conventional programmed electrical stimulation techniques. The ventricular origin of the patient's arrhythmias was confirmed by His bundle recordings. A Medtronic model 5652 stimulator was used to pace the right ventricle at a cycle length (S_1S_1) of 500 ms and to introduce up to 2 extrastimuli at twice diastolic threshold. Coupling intervals were serially shortened by 5 ms until sustained ventricular tachycardia occurred or ventricular refractoriness was encountered. If sustained ventricular tachycardia could not be elicited with the electrode catheter positioned at the right ventricular apex, the catheter was moved to the pulmonary outflow tract and the protocol was repeated. This same protocol was used with the patient in the drug-free state and during encainide treatment.

Analytical: Plasma serum samples were assayed using a high-performance liquid chromatography system described by Mayol and Comer,[11] which separates and quantifies encainide, O-demethyl encainide and other metabolites (N-demethyl encainide, O, N-didemethyl encainide and 3-methoxy-O-demethyl encainide). This assay was modified to use S-15531 (supplied by Riker Laboratories) as an internal standard.

Results

Table I describes the population studied. Patients in group I had sustained ventricular tachycardia; 8 patients (group Ia) had previous myocardial infarction and sustained ventricular tachycardia that would not self-terminate and required repeated cardioversions, and 3 patients (Group Ib) had no previous myocardial infarction or coronary artery disease and sustained ventricular tachycardia that did self-terminate). Group II consisted of 26 patients with symptomatic, complex, nonsustained ventricular arrhythmias: 21 with episodes of nonsustained ventricular tachycardia, defined as 3 to 100 consecutive ventricular beats at a cycle length of shorter than 600 ms) and 5 patients with recurrent ventricular couplets but no evidence of ventricular tachycardia.

Response to encainide therapy: None of the patients in group Ia had a satisfactory response to en-

cainide therapy, and in 4 patients ventricular arrhythmias actually worsened. However, 2 of these patients had had paradoxical increases in arrhythmia frequency with other antiarrhythmic drugs, 1 with mexiletine and 1 with aprindine.

One patient in group Ia died while taking encainide (intractable ventricular fibrillation). Of the other 7 patients in groups Ia, no effective therapy could be found for 1, who died in hospital on other medications, and 6 patients finally responded to other antiarrhythmic agents. Response was complete in 3 patients (procainamide-dilantin combination in 2 and bretylium in 1) and only partial in 3 (ventricular tachycardia became much less frequent and slower). Complete responders have been arrhythmia-free for 26 months. During follow-up of the 3 patients with a partial response, 1 died (during procainamide treatment) and 2 patients continued to have episodes of sustained ventricular tachycardia during a 12-month follow-up (receiving procainamide-dilantin combination treatment).

Twenty-four of the 29 remaining patients (group Ib and group II) had an excellent antiarrhythmic response (defined as abolition of ventricular tachycardia and more than 85% suppression of VPCs) and were discharged with encainide therapy. Side effects prevented therapy in 5 patients: in 2 bundle branch block developed, 1 had AV nodal Wenckebach periodicity and 1 had sinus pauses. Before encainide treatments, 3 of these 4 patients had preexisting conduction abnormalities (PR longer than 0.2 second or QRS longer than 0.12 second). In the other nonresponding patient, diplopia developed at maximal allowable dosages of encainide (125 mg orally every 6 hours), and the patient was subsequently shown not to produce the metabolite, O-demethyl encainide. Fourteen of the original 24 responding patients continue to receive encainide at a mean follow-up of 21.5 months (range 1 to 40). Three patients in group II died, all of whom had poor left ventricular function (mean ejections fraction 32%); their deaths were not sudden and were preceded by progressive congestive heart failure. Encainide was discontinued in 7 other patients during follow-up: in 2 because of outpatient syncopal episodes associated with right bundle branch block (no arrhythmia could be documented during prolonged ambulatory monitoring), in 1 because of exercise-induced polymorphic ventricular tachycardia (not present during placebo), in 2 because atrial fibrillation developed, in 1 because of diplopia, and in 1 because of a skin exanthem.

Worsening of arrhythmias: Arrhythmias worsened in 7 patients: 4 in group Ia and 3 in groups Ib and II ($p < 0.01$, χ^2 test). Paradoxical worsening of arrhythmias was identified by the presence of 1 of 4 criteria: (1) Four patients in group Ia showed a striking increase in the frequency of spontaneous episodes of sustained ventricular tachycardia. One of these patients died with intractable ventricular fibrillation and 3 patients had sustained ventricular tachycardia that persisted for hours. (2) In 2 of 11 patients studied (1 patient in group Ia and 1 in group II), sustained ventricular tachycardia was easier to induce by programmed electrical stimulation. All patients appeared to have suppression of spontaneous arrhythmias at the time of electrophysiologic study; however, patients in group Ia had sporadic arrhythmias and spontaneous ventricular tachycardia occurred late during encainide treatment that was unrelated to programmed electrical stimulation. Sustained ventricular tachycardia resulted from the application of 2 extrastimuli in all 3 patients in group Ia at baseline. This same endpoint could still be induced in all 3 patients during encainide treatment, but in 1 patient only 1 extrastimulus was required. In none of the patients in group II was sustained ventricular tachycardia induced at baseline, but in 1 patient it was induced during encainide treatment. (3) In 3 of 4 patients in whom sustained ventricular tachycardia could be terminated with ventricular burst pacing (all in group Ia), this technique was no longer successful during encainide treatment. (4) Nonsustained ventricular tachycardia developed during treadmill exercise testing in 3 of 8 patients in group II who underwent this evaluation during encainide treatment. No patient in group II had had ventricular tachycardia during exercise testing while receiving placebo or antiarrhythmic treatment other than encainide.

TABLE II Relation Between Presence or Absence of Paradoxical Worsening of Arrhythmias in Group Ia to Dosage, Plasma Concentration and Electrocardiographic Interval Change

	Paradoxical Events (n = 4)	VT Nonresponsive (n = 4)
Mean dose (mg/day)	300 ± 90 (range 181–400)	284 ± 67 (range 200–362)
Encainide conc. (ng/ml) when treatment stopped	977 ± 847 (range 81–1,765)	191 ± 141 (range 31–302)
ODME conc. (ng/ml) when treatment stopped	458 ± 481 (range 24–977)	NA
Change in QRS duration (sec) from baseline	0.06 ± 0.03 (range 0.04–0.11)	0.04 ± 0.02 (range 0.01–0.05)
Change in QTc interval (sec) from baseline	0.03 ± 0.05 (range 0.03–0.08)	0.11 ± 0.08 (range 0.05–0.16)
Change in JTc interval (sec) from baseline	0.05 ± 0.02 (range 0.03–0.07)	0.07 ± 0.07 (range 0.03–0.19)

conc. = concentration; NA = not available; ODME = O-demethyl encainide; VT = ventricular tachycardia.

Dosage, concentration, electrocardiographic interval changes and outcome in group Ia: Table II lists the presence or absence of paradoxical events occurring in group Ia related to dosage, plasma concentration and electrocardiographic interval change. Patients in whom paradoxical events developed tended to have higher plasma encainide concentrations and greater prolongation in the QRS duration. However, owing to the small number of patients, no significant relationships could be found.

Discussion

Although encainide is often effective in the treatment of drug-resistant ventricular arrhythmias, we have identified a subset of patients in whom encainide therapy is uniformly not successful and in whom adverse effects occur frequently. Although lack of response to encainide may imply drug resistance, 6 patients had a complete or partial antiarrhythmic response to other

medications. Paradoxical worsening of arrhythmias was not observed during optimal antiarrhythmic therapy. Disparity in antiarrhythmic efficacy among patient subsets may relate both to the nature of the underlying myocardial abnormality and the presumed mechanism of the arrhythmia being treated. The state of the underlying myocardium clearly influences the electrophysiologic effects of a given medication, as shown by the differing electrophysiologic effects of procainamide and lidocaine in normal and in ischemic myocardium.[12–14] Similarly, the postulated mechanism of the arrhythmia being treated can alter efficacy. Several antiarrhythmic agents show a lack of efficacy or paradoxical worsening of reentrant arrhythmias while effectively suppressing automatic arrhythmias.[15–18] We examined the effect of O-demethyl encainide (the active metabolite of encainide) on spontaneous arrhythmias (presumably increased automaticity) and electrically induced arrhythmias (presumably reentrant) occurring 2 days after occlusion-reperfusion injury in dogs.[19] Spontaneous arrhythmias were effectively suppressed, whereas the ability to induce sustained ventricular tachycardia by programmed electrical stimulation was enhanced and ventricular fibrillation threshold was lowered. In contrast, O-demethyl encainide raised the ventricular fibrillation threshold in normal animals. The results seen in the present study in humans are in keeping with these observations in animals. Although encainide appears to be effective in treating many patients with drug-resistant ventricular arrhythmias (with a spectrum of myocardial abnormalities and arrhythmic mechanisms), patients with sustained ventricular tachycardia associated with previous myocardial infarction constitute a subset of patients who do not respond to encainide and in whom paradoxical worsening of arrhythmias occurs frequently. Patients who have sustained ventricular tachycardia associated with segmental wall motion abnormalities have been found to have delayed and nonhomogeneous intraventricular conduction in the border of infarct zones.[20–22] Myocardial abnormalities that predispose to nonhomogeneous intraventricular conduction combined with medications that markedly delay intraventricular conduction (encainide and O-demethyl encainide) may create conditions ideal for the development of reentry circuits.[7]

Mason et al[6] reported their experience in 38 patients with drug-resistant ventricular tachycardia and reported results that contrast with ours. All of their patients were initially considered responsive to encainide therapy, although 17 were withdrawn from encainide during the first 6 months of follow-up. The clinical characteristics of patients who did not have a persistent outpatient antiarrhythmic response were not detailed. In their study, the 4 patients who had paradoxical worsening of ventricular arrhythmias with encainide also had previously received repeated cardiopulmonary resuscitation.

The manner in which encainide is administered may also affect the resultant incidence of efficacy or toxicity. Given the information that encainide had a half-life of less than 3 hours in most patients, the dosage of encainide was at times rapidly increased in this study to control life-threatening ventricular arrhythmias. However, new analytic techniques have allowed the identification of metabolites of encainide[11] that appear to contribute to the pharmacologic effects of encainide (electrophysiologic effects[19,23,24] antiarrhythmic response[25–27] and possible adverse effects[19]). These active metabolites of encainide appear to have delayed elimination dosage relative to the parent, and rapid increases in encainide dosage (before reaching steady-state conditions for the metabolites) may result in delayed excessive accumulation of the metabolites. This may explain the paradoxical worsening of ventricular arrhythmias often seen in patients with life-threatening arrhythmias. In support of this possibility we showed that a high concentration (more than 300 ng/ml) of O-demethyl encainide (the predominant metabolite in most patients[28]) lowers the fibrillation threshold in an ischemic canine model[19] and predisposes to ventricular tachycardia induced by programmed electrical stimulation (presumably a reentrant mechanism). Owing to its complex metabolic profile, encainide appears ill-suited as an intravenous agent for treating life-threatening ventricular arrhythmias. Dosage increases of encainide should be considered only after steady-state conditions have been achieved for both the parent compound and its metabolites (several days).

In the present study relatively few patients with sustained ventricular tachycardia were evaluated during encainide treatment. If more patients had been studied, a proportion of patients (like those in group Ia) might have responded to encainide. However, because paradoxical worsening of arrhythmia was frequent and alternative medications were effective, additional patients like those in group Ia were not treated with encainide.

Exercise-Induced Left Bundle Branch Block and Its Relation to Coronary Artery Disease

CHARLES VASEY, MD, JACQUELINE O'DONNELL, MD, STEPHEN MORRIS, MD, and PAUL McHENRY, MD

The records of 2,584 consecutive patients who underwent both treadmill exercise testing and coronary cineangiography were reviewed to determine the relation between exercise-induced, acceleration-dependent left bundle branch block (LBBB) and the presence of coronary artery disease (CAD). Rate-dependent LBBB during exercise was identified in 28 patients (1.1%), who were categorized according to their presenting symptoms: classic angina pectoris, atypical chest pain, symptomatic cardiac arrhythmia and asymptomatic. Asymptomatic patients underwent a screening exercise test. CAD was present in 7 of 10 patients who presented with classic angina pectoris, but 12 of 13 patients presenting with atypical chest pain had normal coronary arteries. All 10 patients in whom LBBB developed at a heart rate of 125 beats/min or higher were free of CAD, whereas 9 of 18 patients in whom LBBB developed at a heart rate of less than 125 beats/min had CAD. Normal coronary arteries were present in 3 patients who presented with angina and in whom both chest pain and LBBB developed during exercise. It is concluded that (1) patients who present with atypical chest pain in whom rate-dependent LBBB develops on the treadmill are significantly less likely to have CAD than patients who present with classic angina; (2) the onset of LBBB at a heart rate of 125 beats/min or higher is highly correlated with the presence of normal coronary arteries, regardless of patient presentation; and (3) patients with angina in whom both chest pain and LBBB develop during exercise may have normal coronary arteries.

(Am J Cardiol 1985;56:892–895)

The clinical significance of acceleration-dependent, exercise-induced left bundle branch block (LBBB) is controversial. Several investigators[1–4] have documented the coexistence of acceleration-dependent LBBB during stress testing and angiographically normal coronary arteries. However, Wayne et al[5] suggested that exercise-induced LBBB is almost always associated with demonstrable cardiac abnormalities, most frequently coronary artery disease (CAD).[5] To further evaluate these conflicting observations we reviewed the records of 2,584 consecutive patients at our institution who underwent treadmill exercise testing, left ventriculography and coronary cineangiography. We identified 28 patients (1.1%) who had acceleration-dependent LBBB during stress testing. This study examines the relation between exercise-induced, rate-dependent LBBB and the presence and extent of CAD in these patients.

Methods

Standard criteria were used to define complete LBBB, including a QRS duration of 0.13 second or longer. Normal conduction was recorded on the electrocardiogram at rest before the initiation of exercise testing in all patients. We required that LBBB result from an acceleration of the heart rate and not a single premature stimulus.

Treadmill exercise testing was performed using a modified Balke protocol. Coronary cineangiography was carried out using the Judkins technique. All single-plane left ventriculograms were recorded in the right anterior oblique position. Left ventricular function was evaluated by segmental wall motion analysis of the ventriculograms and was considered abnormal if any 1 segment demonstrated abnormal systolic motion. Significant coronary artery disease was defined as at least a 50% reduction in the luminal diameter of the left anterior descending, left circumflex, left main or right coronary arteries.

Statistics: The relation between presenting symptoms and the presence or absence of CAD was assessed using Fisher's exact test, as was the relation between heart rate at the onset of LBBB and the presence or absence of CAD.

Patients: Table I is a list of the initial indication for exercise testing, medications at the time of testing, and the results of treadmill testing, coronary cineangiography and left ventriculography. In all 28 patients complete LBBB developed during exercise testing. The initial treadmill exercise test is reported in instances where patients had more than 1 stress test, except in cases where LBBB occurred only during a single, subsequent examination. Among the 8 patients who underwent more than 1 test, 4 had LBBB only 1 time, whereas 2 showed aberrant conduction at nearly identical heart rates

Atypical chest pain	13	1	12	
Cardiac arrhythmias	3	1	2	
Asymptomatic	2	0	2	
Total	28	9	19	

CAD = coronary artery disease; +CAD = at least 1 vessel with ≥50% stenosis; −CAD = no lesion ≥50%; MI = myocardial infarction.

and 2 at significantly slower heart rates during repeat testing. All patients were white; 19 were men and 9 were women. They were 29 to 70 years old (mean 53).

Patients were classified according to the initial indication for exercise stress testing. These classifications were: (1) patients with typical angina pectoris or previously documented myocardial infarction, (2) patients considered to have atypical chest pain, (3) patients studied for symptomatic cardiac arrhythmias, and (4) asymptomatic patients undergoing a screening exercise test.

Results

Arteriographic studies revealed no significant CAD in 19 of the 28 patients (68%); 15 of those 19 were believed to have normal wall motion by left ventriculography. The left ventriculogram was considered to be normal in 19 of the 28 patients, 4 of whom had significant CAD (Table I). In only 3 patients (11%) did ST-segment changes suggestive of ischemia develop before the onset of LBBB. Repolarization abnormalities were observed in 4 patients after the restoration of normal conduction, although in several patients interpretation of postexercise ST-segment changes were precluded by the persistence of aberrant conduction beyond the 6-minute period of observation.

The extent and location of coronary artery narrowing among the 9 patients with CAD was highly variable (Table I).

The indication for initial treadmill exercise testing and the results of left ventriculography and coronary cineangiography are compared in Table II. Table III is a comparison of the initial indication for exercise testing and the presence or absence of CAD. Significant CAD was present in 7 of 10 patients who had had a prior myocardial infarction or were believed to manifest classic angina pectoris. Only 1 of 13 patients referred for diagnostic evaluation of atypical chest pain had CAD; 11 of these patients also had normal left ventriculographic findings. This difference in the prevalence of CAD between patients with classic angina and patients with atypical chest pain was highly significant ($p < 0.004$). Both of the asymptomatic subjects who underwent arteriographic studies because of an abnormal treadmill exercise test were normal. The ventriculograms were abnormal in all 3 patients with symptomatic cardiac arrhythmias, but only 1 patient had significant CAD.

Figure 1 depicts the relation between the heart rate at the onset of LBBB and the presence or absence of CAD. Whereas aberrant conduction developed at variable heart rates in patients without significant CAD, in all patients with CAD LBBB developed at a heart rate of less than 125 beats/min. Exercise-induced LBBB at a heart rate of 125 beats/min or greater was more likely to develop in patients without CAD ($p < 0.01$).

Chest discomfort developed in 12 of 28 patients during or soon after exercise. Seven of these patients had normal coronary arteries and 5 had significant CAD. No consistent relation was observed between the onset of chest discomfort and the initiation of aberrant conduction during exercise. Normal coronary arteries were found in 3 patients with typical angina or previously documented myocardial infarction in whom chest pain and rate-dependent LBBB developed with exercise.

Discussion

An accurate determination of the clinical significance of exercise-induced, acceleration-dependent LBBB is important. Rate-dependent LBBB may be a reflection of underlying myocardial dysfunction, intrinsic disease of the cardiac conducting tissues or a compromised coronary circulation. Before the advent of coronary arteriography, rate-dependent LBBB was believed to result most often from arteriosclerotic CAD.[6–10] More recently, several investigators have reported patients with exertional chest pain, exercise-induced LBBB and normal coronary arteries.[1,3,4] Conflicting observations have also been reported. Wayne et al[5] found angiographically proved CAD in 7 of 11 patients with exercise-induced LBBB, and 1 other patient had documented coronary spasm. Two patients had primary myocardial disease and only 1 of their patients was considered to be without evidence of cardiovascular disease. They concluded that exercise-induced bundle branch block is almost always associated with cardiovascular disease, and usually with CAD.

Our results help to clarify these contrasting observations and provide a means of identifying patients with exercise-induced LBBB and normal coronary arteries. In our study, of 28 patients with exercise-induced, acceleration-dependent LBBB, 19 (68%) were free of CAD. Coronary cineangiographic results were normal in 12 of 13 patients with atypical chest discomfort. Only 3 of 10 patients with a clinical diagnosis of angina pectoris or a prior myocardial infarction had normal coronary arteries, and only 2 had normal ventriculographic findings as well. Thus, exercise-induced LBBB was associated with abnormal findings at cardiac catheterization in less than half of our patients, although, as one might expect, most patients with classic angina did have significant CAD, whereas patients with atypical chest pain did not. These findings indicate the need to categorize patients with exercise-induced LBBB based on the nature of their presenting symptoms and, as such, reinforce the importance of accurate historical information.

Our study results suggest that the presence of normal coronary arteries can be predicted with increased specificity by examining the exercise heart rate at the onset of aberrant conduction. None of the 10 patients in whom LBBB developed at a heart rate of 125 beats/min or greater had CAD; 7 had normal findings and 3 had segmental wall motion abnormalities on the left ventriculogram at rest. A review of previous reports provides further support for this heart rate criterion. Previous studies[1–5,12] include an additional 23 cases of exercise-induced LBBB in patients undergoing cineangiography; in 6 of these patients LBBB developed at exercise heart rates of 125 beats/min or greater and 5 had normal coronary arteries.

Surprisingly, 3 of 8 patients with classic angina pectoris who had chest pain and LBBB with exercise had normal coronary arteries. All 3 patients with a history of atypical chest pain in whom LBBB and chest discomfort developed during treadmill testing were free of CAD. These findings are consistent with those reported by others.[1,3,4] However, the cause of chest pain in these patients is not known. Virtanen et al[3] reported 7 patients in whom exercise-induced LBBB, chest pain and paradoxical septal motion simultaneously developed, without overt evidence of myocardial ischemia. They proposed that the chest discomfort resulted from abnormal septal motion. Kafka and Burggraf[4] also observed the simultaneous onset of exercise-induced LBBB and chest pain in a patient with no apparent ischemia, but they did not document a coexistent change in septal motion.[4] In our patients there was no consistent relation between the onset of chest discomfort and the onset of left bundle branch aberrancy.

The clinical significance of exercise-induced LBBB also remains poorly defined. Although several investigators suggest that acceleration-dependent LBBB results most often from arteriosclerotic CAD,[6–11] LBBB during exercise clearly occurs in the presence of angiographically normal coronary arteries. Data from the Framingham study indicated that in as many as one-third of patients in whom permanent LBBB develops, clinical congestive heart failure develops a mean of 3.3 years after the onset of LBBB.[13] In many cases the LBBB was the first clinical sign of a developing cardiomyopathy. Exercise-induced LBBB, therefore, may also be an early manifestation of a developing, nonischemic cardiomyopathy.

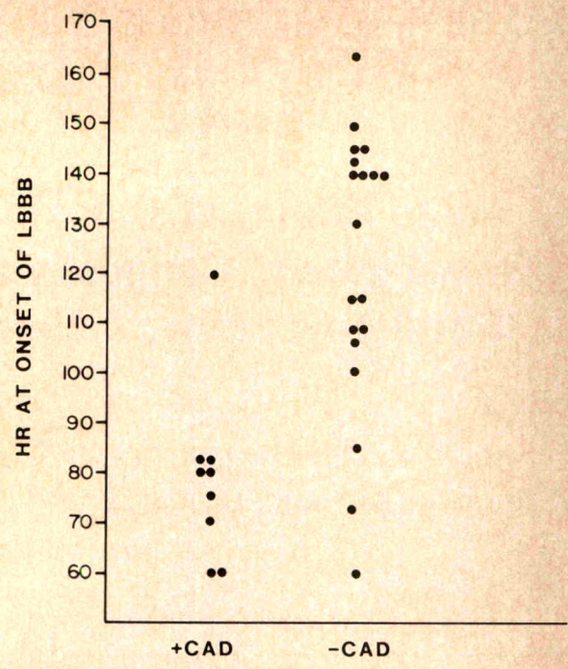

FIGURE 1. Heart rate (HR) at the onset of left bundle branch block (LBBB) relative to the presence or absence of coronary artery disease (CAD). No patient with CAD had exercise-induced LBBB at a heart rate of 125 beats/min or greater.

One limitation of this study is that the data were collected retrospectively. In addition, much of the cardiac catheterization data were derived from subjective visual interpretation by different angiographers, and hence is subject to interobserver variability. Ventriculography alone can legitimately be criticized as an incomplete means of evaluating left ventricular function. Finally, the presence of coronary artery spasm was not definitely excluded in most patients with normal coronary cineangiographic findings.

Acute Effects of Digoxin on Total Systemic Vascular Resistance in Congestive Heart Failure Due to Dilated Cardiomyopathy: A Hemodynamic-Hormonal Study

HILLEL S. RIBNER, MD, DOMINIC A. PLUCINSKI, MD, ANN-MING HSIEH, MD, DENNIS BRESNAHAN, MD, AGOSTINO MOLTENI, MD, PhD, JOSEPH ASKENAZI, MD, and MICHAEL LESCH, MD

The effects of the digitalis glycosides on systemic vascular resistance (SVR) in patients with congestive heart failure (CHF) are controversial. Most investigators report a reduction in total SVR, an action that has been attributed primarily to withdrawal of elevated sympathetic tone. Direct proof of this hypothesis is lacking, however, and the roles played by the renin-angiotensin-aldosterone and vasopressin systems have not been fully explored. Moreover, in several studies of patients with CHF, SVR did not decrease after the administration of digitalis. To clarify these issues, the hemodynamic and hormonal effects of digoxin were correlated in 11 normotensive men in sinus rhythm with CHF due to dilated cardiomyopathy. Patients were evaluated at rest and during submaximal exercise before and 6 hours after the intravenous infusion of 1.0 mg of digoxin (mean serum concentration 1.7 ng/ml). With digoxin therapy, heart rate, pulmonary wedge pressure and right atrial pressure declined and cardiac output increased. Although vasopressin was unchanged, both plasma norepinephrine concentrations and plasma renin activity decreased, the reduction in norepinephrine correlating with the increase in cardiac output. Despite these hemodynamic and hormonal effects, there was no change in total SVR at rest or during exercise. It is concluded that the improvement in cardiac function with digoxin in this patient group was a result of the inotropic properties of the drug, without an associated reduction in impedance. The failure of total SVR to decrease despite decreases in plasma norepinephrine levels and plasma renin activity might be explained by concomitant digitalis-induced vasoconstriction, impaired ability of arterioles to dilate in CHF, or offsetting alterations in other vasoactive hormone systems.

(Am J Cardiol 1985;56:896–904)

The ability of therapeutic agents to improve cardiovascular function relates to their actions on both the peripheral vasculature and the heart. The digitalis glycosides, long recognized as having potent inotropic properties, have also been shown to constrict arterioles in the normal experimental animal[1,2] and to increase vascular resistance in the nonfailing human circulation.[3]

In contrast, it is generally accepted that digitalis does not cause vasoconstriction in patients with congestive heart failure (CHF). The nature of the resistance response to digitalis in patients with CHF is controversial, however. Most investigators have documented reductions in systemic vascular resistance (SVR),[4–12] leading to the conclusion that the glycosides owe their beneficial effects in patients with CHF both to enhancement of cardiac contractility and to lowering of the impedance to ventricular ejection.[13,14] However, a number of studies have demonstrated no decrease in SVR even when other hemodynamic variables changed considerably.[6,15–19] The reasons for the conflicting data are not known, but may be in large part a result of the complex nature of the CHF syndrome as well as the difficulty in obtaining adequate standardization of clinical parameters in the study population.[15]

It is unclear why drugs that are inherently vasoconstrictive fail to increase, or even reduce, vascular resistance in patients with CHF. The most frequently proposed mechanism is that in addition to their direct vascular effects, the digitalis glycosides mediate a withdrawal of the elevated sympathetic tone characteristic of this syndrome.[4,5,13,20] However, direct proof of this hypothesis is not available, and changes in plasma norepinephrine concentrations after administration of digitalis have not been investigated. A reduction in plasma renin activity (PRA) was recently reported,[21] but the responses to digitalis of the vasopressin system (the activity of which is also increased in patients with CHF[22,23]) have not been explored. Moreover, in no CHF study have changes in vasoactive hormone levels with digitalis been correlated with the hemodynamic actions of the drug.

In view of these uncertainties with regard to the hemodynamic and neurohumoral responses to digitalis in patients with CHF, this study was designed with a 2-fold purpose: to evaluate the acute effects on vascular resistance of therapeutic concentrations of a digitalis glycoside in a well-defined group of normotensive patients with chronic, stable, myocardial failure in sinus rhythm; and to correlate those actions with simultaneous changes in the blood levels of hormones known to affect arteriolar smooth muscle tone. The results indicate that despite significant reductions in the vasoconstrictive hormone levels, there was no change in total SVR in this patient population.

Methods

Criteria for patient selection: The study cohort consisted of 11 men with myocardial failure due to alcoholic or idiopathic cardiomyopathy who fulfilled the following clinical and hemodynamic requirements: typical symptoms of left-sided heart failure, with or without right-sided failure, at least 6 months in duration; radiographic and echocardiographic criteria for cardiomegaly; the presence of normal sinus rhythm; systemic arterial mean pressure greater than 65 mm Hg but less than 110 mm Hg at rest; left ventricular ejection fraction less than 35% as determined by equilibrium radionuclide scanning; cardiac index 2.5 liters/min/m^2 or less; and pulmonary wedge pressure 12 mm Hg or more at rest in the supine position. Reasons for exclusion from the study included pericardial, restrictive or valvular heart disease (except for mild tricuspid or mitral regurgitation thought to be due solely to ventricular dilation); acute exacerbation of heart failure within the previous 4 weeks; endocrinologic disorder, including diabetes mellitus; clinically important pulmonary disease (excluded by pulmonary function studies when necessary); more than mild renal or hepatic dysfunction (creatinine greater than 2.0 mg/dl, bilirubin more than 2.0 mg/dl, serum glutamic oxaloacetic transaminase more than 60 IU/liter); and inability to adhere to the prescribed diet. All patients had either never received digitalis or had had such therapy discontinued for at least 2 weeks.

Stabilization period: Subjects were admitted to the clinical research center 5 to 7 days before the study, at which time all remaining medications, including diuretic drugs, were stopped. No smoking was permitted. A strict metabolic diet providing 33 mEq of sodium and 60 mEq of potassium per day was prescribed (American Dietary Products), and patients were observed until body weights were stable (less than 2% variation) for at least 2 successive days.

Drug intervention: Thirty-six hours before digoxin administration, a balloon-tipped, triple-lumen, thermodilution catheter was advanced to the pulmonary artery under fluoroscopic control, and a short plastic catheter was inserted percutaneously into the radial artery. Subsequent procedures were conducted in a quiet, private room where every effort was made to ensure a minimum of emotional stimulation. In each instance, experimental observations were made at least 3 hours after eating. Twenty-four hours before drug administration, the first of 2 sets of control hemodynamic and hormone measurements was made. Heart rate, cardiac output, and systemic arterial, pulmonary arterial, pulmonary wedge and right atrial pressures were determined in all patients after at least 1 hour of sitting at rest in a comfortable chair. To document stability of the control data, hemodynamic measurements were repeated at intervals of 20 to 30 minutes until there was less than 10% variability in cardiac output. Control hemodynamic variables were then measured during 5 to 10 minutes of pedaling in the sitting position on a bicycle ergometer at a constant load of 15 W (50 rpm). Simultaneous with the rest and exercise hemodynamic studies, venous blood was drawn through the right atrial port of the intracardiac catheter for the determination of plasma concentrations of norepinephrine, epinephrine and arginine vasopressin as well as PRA. To provide insights into the interactions between digitalis and the vasoactive hormones, plasma osmolality and plasma concentrations of sodium and potassium were measured and serum was collected for analysis of aldosterone and adrenocorticotropic hormone (ACTH).

On the morning after these initial studies, baseline hemodynamic and hormonal measurements were repeated. Immediately thereafter (at approximately 12 PM), 1.0 mg of digoxin, diluted to 50 ml in 5% dextrose in water, was infused into the right atrium by infusion pump over a period of 30 to 40 minutes (mean dose 0.015 mg/kg body weight). Six hours later, hemodynamic studies at rest and during exercise were performed for a third time, and blood was again drawn simultaneously for hormonal, osmolality and electrolyte analyses.

Serum digoxin levels were determined in all patients at rest during the second control period and 6 hours after completion of the digoxin infusion. In 8 patients, digoxin levels were also measured 1 hour after infusion.

Hemodynamic techniques: Heart rate was measured directly from a continuously monitored electrocardiogram. Systemic arterial and intracardiac pressures were obtained using Gould P23 Id pressure transducers calibrated against mercury, and were recorded on a multichannel physiologic recorder (Electronics for Medicine model VR6). The reference for all pressures was a plane 5 cm below the sternal angle. Mean pressures were measured using electronic damping. Cardiac output was determined by the thermodilution technique using an Edwards Laboratory computer (model 9520A) and 10-ml injections of iced 5% dextrose in water. Each value represents the average of 3 consecutive injections. In our laboratory, cardiac output measurements are reproducible to within 5%. Total SVR was calculated as [(systemic arterial mean pressure − mean right atrial pressure)/cardiac output] × 80.

Hormonal, digoxin and electrolyte analyses: Blood for chemical determinations was drawn into chilled tubes containing the proper anticoagulant (if any), centrifuged within 10 minutes at 2°C and stored at −80°C until analyzed. Catecholamine levels were measured in the first 2 patients by a radioenzymatic assay (Cat-a-Kit,™ Upjohn Diagnostics) and in the remaining patients by liquid chromatography.[24] Correlation coefficients between the 2 methods are 0.94 and 0.90 for norepinephrine and epinephrine, respectively, and all

BSA = body surface area; CHF = congestive heart failure; CI = cardiac index; CM = cardiomyopathy; EF = ejection fraction; NYHA = New York Heart Association; PWP = pulmonary wedge pressure; SD = standard deviation.

values are reported without adjustment for method. PRA was estimated by quantitation of generated angiotensin I (Rianen™ Radioimmunoassay System, New England Nuclear). Concentrations of arginine vasopressin,[25] aldosterone, ACTH and digoxin were determined by radioimmunoassay. There was no cross reactivity between digoxin and any of the hormones tested. Plasma osmolality was determined by freezing point depression (model 3DII osmometer, Advanced Instruments), and plasma electrolytes by flame photometry.

Statistical calculations: Sequential changes in hemodynamic and hormonal variables were evaluated using the 2-tailed *t* test for paired data. Correlation coefficients were established using linear regression analysis of the bivariate normal distribution. Results were considered significant at the 5% level. Except where noted, values are reported as mean ± standard error of the mean.

Results

Patients: Baseline clinical and hemodynamic characteristics of the study subjects are listed in Table I. All patients achieved a stable weight with dietary therapy alone. In no instance did symptoms worsen during the drug-free stabilization period, nor was specific therapy required before hemodynamic intervention.

Hemodynamic findings (sitting position) (Tables II and III): There were no significant differences in hemodynamic measurements between the 2 sets of control observations (data not shown). With digoxin, heart rate decreased significantly both at rest and during exercise. Cardiac output increased an average 13% at rest and 12% during exercise. Systemic arterial mean pressure increased significantly at rest, but pulmonary arterial diastolic, pulmonary wedge and right atrial pressures decreased at both levels of activity. No significant change occurred in total SVR at either rest or with exercise.

Hormonal observations (Tables II and III): There were no significant differences in hormone levels between the 2 sets of control measurements (data not shown). After administration of digoxin, the plasma norepinephrine concentration decreased an average of 28% at rest and 26% during exercise, declining in all instances in which it was measured. Plasma epinephrine did not change. Mean PRA decreased 32% at rest and 50% during exercise. At rest, PRA decreased in 8 patients, increased in 1 patient, and was essentially unchanged in the remaining 2. During exercise, all but 1 patient had a decrease in PRA after administration of digoxin.

The decline in plasma norepinephrine concentration correlated significantly with the increase in cardiac output both at rest and during exercise (Fig. 1). It also correlated with the reduction in mean right atrial pressure ($r = 0.72$, $p < 0.05$ at rest; $r = 0.66$, $p = 0.05$ during exercise). The reduction in PRA correlated with

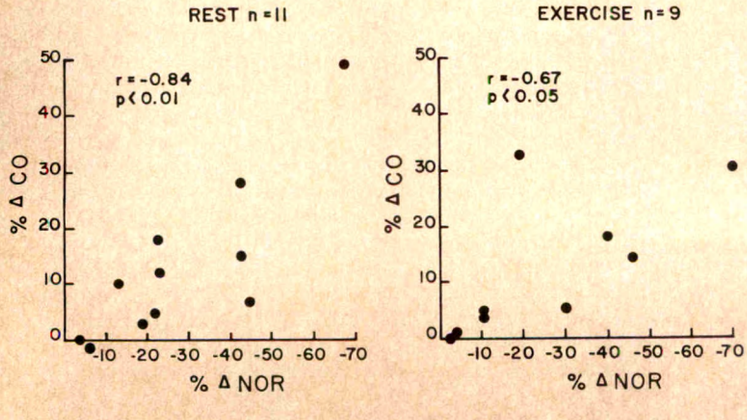

FIGURE 1. Correlations between percentage changes in cardiac output (% ΔCO) and in plasma norepinephrine concentration (% ΔNOR) after digoxin therapy.

the increase in systemic arterial mean pressure during exercise, but there was no significant correlation at rest (Fig. 2).

Data on plasma arginine vasopressin and on serum aldosterone and ACTH were available in all 11 patients at rest and in 8 patients during exercise. Although arginine vasopressin tended to decrease both at rest and during exercise after digoxin was given, neither decrease was significant. Aldosterone declined 21% at rest, but was unchanged during exercise. ACTH was unaltered at both levels of activity. Plasma osmolality and plasma sodium and potassium concentrations averaged 279 mosm/kg, 134 mEq/liter, and 4.3 mEq/liter, respectively, at control rest, and remained constant with digoxin therapy.

Serum digoxin concentrations (Table II): The serum digoxin concentration was below the limits of the assay in all patients during the control period. Six hours after completion of the digoxin infusion, the serum digoxin level averaged 1.7 ± 0.1 ng/ml for the entire group of 11 patients. In the 8 patients with sequential digoxin determinations, the drug level was 6.6 ± 1.6 ng/ml at 1 hour and 1.7 ± 0.2 ng/ml at 6 hours after infusion ($p < 0.02$ for the difference between the 1-hour and 6-hour measurements).

Discussion

Total SVR is known to be elevated in patients with CHF, but the precise mechanisms of arteriolar constriction are not understood. Although structural abnormalities of the vessel wall may play an important role, there is also strong evidence for participation by a number of vasoactive neurohormonal systems. Plasma concentrations of norepinephrine are abnormally elevated in patients with CHF at rest[26–28] and during submaximal exercise,[26,29,30] and are presumed to reflect enhanced activity of the sympathetic nervous system.[31] The increases in plasma norepinephrine levels in the basal state are directly related to the severity of symptoms,[27] intracardiac filling pressures[26,28] and total SVR,[28] and are inversely proportional to the cardiac output.[26,28] PRA and arginine vasopressin levels are also elevated in many patients with heart failure,[22,23,28,32] although correlations between intracardiac pressures, total SVR and cardiac output on the one hand and these plasma hormones on the other have been poor in many series.[22,32]

Digitalis glycosides increase total SVR in normal persons[3,33] and constrict arterioles in the coronary,[33] skeletal muscle,[1,2,4,20] renal[20] and possibly mesenteric[20,34] beds. Several mechanisms have been implicated in the digitalis-induced vasoconstriction. The glycosides stimulate sympathetic outflow from the central nervous system,[35] promote release of endogenous catecholamines from terminals of adrenergic nerves,[36] prevent subsequent catecholamine reuptake,[37] and potentiate the reactivity of vascular smooth muscle to released norepinephrine.[38,39] In addition, digitalis has a direct vasoconstrictive effect that is inhibited by calcium-blocking agents.[2,38]

In contrast to the vasoconstrictive action uniformly observed in the normal circulation, the reported influence of digitalis glycosides on SVR in CHF in humans has been variable. Most studies, particularly those appearing before 1965, document a reduction in systemic resistance with digitalis.[4–12] In contrast, failure of resistance to decrease was noted as early as 1950 by Bayliss et al,[15] and this finding was confirmed 8 years later by Werko et al.[16] In a series of 15 patients with compensated CHF, Selzer and Malmborg[6] found no alteration in total systemic resistance with digoxin in a subset of 5 subjects who at baseline were clinically and hemodynamically indistinguishable from the 10 in whom resistance declined. Lack of reduction in SVR might have been expected in these studies, because in none did cardiac output or left ventricular filling pressures change significantly. However, subsequent investigations reported constancy of vascular resistance even in the face of clear enhancement of ventricular function.[17–19] Variability in the resistance responses to digitalis has been emphasized by Cohn et al,[40] who found that although resistance decreased in 4 of 8 patients with CHF, it actually increased in the other 4.

To some extent such conflicting results may relate to the definition of resistance—total systemic resistance vs total SVR—used by individual workers. However, differences in definition do not account for the observed discrepancies in the resistance response, because both

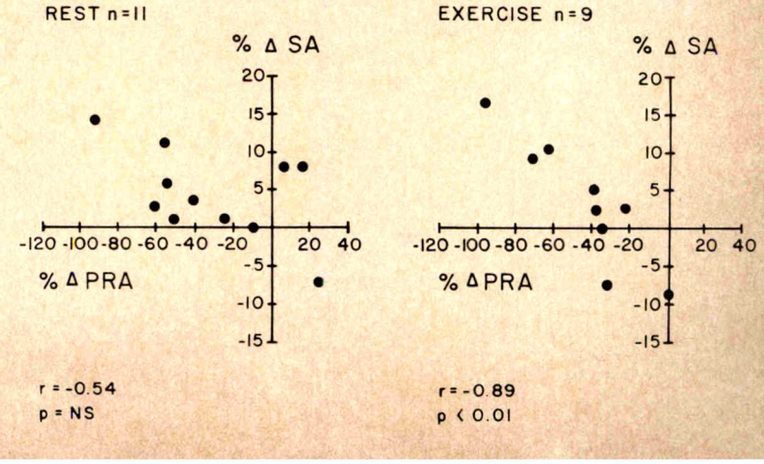

FIGURE 2. Correlations between percentage changes in systemic arterial mean pressure (% ΔSA) and in plasma renin activity (% ΔPRA) after digoxin therapy. NS = not significant.

calculated forms of resistance have been variously reported to either decrease or remain unchanged after digitalis. A partial explanation may be the heterogeneity in the causes and severity of CHF, as well as in cardiac rhythm, which has characterized most investigations to date. Thus, many series have included acutely ill patients or those with stenotic valvular disorders, cor pulmonale, uncontrolled hypertension or high-output states in addition to ischemic or cardiomyopathic disease. The timing of hemodynamic measurements may also affect the experimental observations. After the intravenous bolus administration of digoxin, both serum digoxin levels and tissue concentrations of the drug change rapidly,[41] and equilibrium is fully achieved only after 4 to 5 hours.[42] With a single exception,[18] all previous studies measured changes in vascular resistance less than 2 hours after infusion, when the serum digitalis concentration was expected to be far above the therapeutic range and the results were not necessarily indicative of the steady state.[40] No prior studies evaluating the acute changes in vascular resistance in patients with CHF have reported blood digitalis levels. In the present study, the serum digoxin concentration in 6 patients averaged 6.6 ng/ml at 1 hour after slow infusion of 1.0 mg of digoxin, in contrast to 1.7 ng/ml in the same patients 5 hours later.

To obviate these difficulties, the present protocol was designed to evaluate the short-term relation between cardiac pump function, vascular resistance and vasoactive hormones in a carefully defined group of patients with clinical and hemodynamic evidence of myocardial failure due to cardiomyopathy. Patients with atrial fibrillation, systemic hypertension, pulmonary disease, valvular disease or high-output states were specifically excluded. All subjects were clinically stable (although moderately disabled) at the time of hemodynamic intervention, and measurements were performed 6 hours after infusion. In addition, blood drawn simultaneously with the hemodynamic determinations was assayed for digoxin to assure the achievement of a therapeutic level.

Our observations support those of previous investigators, who found overall hemodynamic improvement with digitalis in patients with CHF. The mean increase in cardiac output 6 hours after digoxin infusion was statistically significant both at rest and during exercise, and was accompanied by decreases in left and right ventricular filling pressures. However, despite the substantial effects on ventricular function, total SVR did not decline significantly with digoxin either at rest or during exercise in this study. The resistance response was consistent: total SVR decreased by more than 10% in only 2 of 11 patients at both rest and during exercise. Improvement in cardiac index and filling pressures in patients with CHF with no change in total systemic resistance was first described with ouabain by Yankopoulos et al[17] in patients at supine rest. In a more recent paper, Murray et al[19] recorded no significant change in any hemodynamic variable with acute ouabain therapy in patients at sitting rest. Total systemic resistance was also unaltered during upright submaximal exercise, although cardiac output increased and left ventricular filling pressure decreased.[19] In the only previous investigation that evaluated hemodynamic effects more than 2 hours after drug infusion, Arnold et al[18] found an increase in cardiac index and a reduction in pulmonary wedge pressure, but no reduction in total systemic resistance with digoxin in patients at supine rest; however, a significant decline in total systemic resistance was demonstrated with maximal supine exercise. In the present study, no change occurred in total SVR at either rest or during submaximal exercise in patients in the sitting position.

Attempts to explain the vascular effects of digitalis in patients with CHF have focused on the known vasoactive neurohumoral systems, but a comprehensive hormonal-hemodynamic investigation has not yet been performed. The present investigation, therefore, sought to evaluate in a systematic manner the responses of the sympathetic nervous, renin-angiotensin-aldosterone and vasopressin systems to digoxin administration in the population with CHF, using blood hormone levels as indicators of neuroendocrine activity. Because both peripheral hormone concentrations[43] and vascular responsiveness[44] may be affected by dietary electrolyte intake or concomitant drug use, sodium and potassium ingestion was strictly controlled and all medications other than the study drug were eliminated. Smoking was discontinued and emotional stimuli were kept to a minimum in order to avoid raising plasma catecholamine concentrations.[45] In addition, catheterization was performed 1½ days before the study and all blood for hormone assays was drawn through the catheter (avoiding the trauma of multiple needle insertions).

Although total SVR did not change in these patients, plasma norepinephrine levels decreased consistently both at rest and during exercise, apparently confirming the postulated withdrawal of sympathetic tone. It is unlikely that the reduction in plasma norepinephrine levels merely reflects a diminution of the subject's anxiety as increased familiarity was gained with the experimental procedure, because control hormone levels were unchanged for at least 24 hours; norepinephrine is relatively insensitive to invasive procedures,[28] and the plasma levels of epinephrine—which have been taken as independent measures of psychic stress[28]—remained stable throughout. Reduction of plasma norepinephrine by digitalis may occur through several routes, including enhancement of norepinephrine uptake by postganglionic nerve terminals[46] and inhibition of norepinephrine synthesis.[35] Activation of high-pressure baroreflexes by a digitalis-induced increase in systemic arterial pressure results in the withdrawal of vasoconstrictive sympathetic discharge to blood vessels in skeletal muscle,[47,48] which can be prevented by carotid and aortic arch baroreceptor denervation[48] or ganglionic blockade.[47] No correlation was found in the present investigation between the decrease in plasma norepinephrine and changes in systemic arterial mean pressure. However, digitalis also sensitizes the arterial baroreceptor mechanism directly, even in the absence of significant increases in cardiac contractile force or arterial pressure.[49,50] In addition, the glycosides enhance the gain of a separate cardiopulmonary baroreflex with

vagal afferents, which induces vasodilation primarily in the renal bed.[51,52] Inhibition of catecholamine release from the adrenal gland[53] is unlikely to have played a significant role in our patients, because plasma epinephrine, the major catecholamine constituent of the adrenal medulla, did not vary with digitalis treatment.

In the present study, a significant correlation was documented between the reduction in plasma norepinephrine levels and the increase in cardiac output. This finding is consistent with the observation that plasma norepinephrine and cardiac output are inversely related in the CHF patient in the baseline state.[26,28] Accordingly, overall improvement in cardiac function owing to the inotropic action of digitalis may in itself lead to a reduction in sympathetic activity, although the mechanisms for this interaction must be determined.

In addition to the reduction in plasma norepinephrine concentrations, the present data revealed a decline in PRA in patients with CHF both at rest and during exercise after digoxin therapy. Similar results have recently been reported by Covit et al[21] in 6 patients with chronic CHF studied at rest. In that report, the percentage reduction in PRA was comparable to the one observed in this study and the nadir of PRA was noted when serum digoxin concentrations were approximately 2 ng/ml. Covit et al[21] also described a decrease in the serum aldosterone concentration, which was confirmed by the current study. Unfortunately, simultaneous hemodynamic measurements were not performed.

In the present investigation, the decrease in PRA with digoxin may have had several origins. The highly significant correlation observed with exercise between the increase in systemic arterial mean pressure and the reduction in PRA is consistent with the inhibitory effect of elevated renal perfusion pressure on renin release,[54] although this relation could not be demonstrated in patients at rest. In addition, the glycoside may have sensitized the cardiopulmonary baroreflex with vagal afferents, augmenting its suppressive effects on renal sympathetic nerve activity and, thus, on renin release.[51,52,55] The possibility also exists that digoxin inhibited renin secretion by a direct effect on the renal cortex as has been shown in both in vitro[56] and in vivo[57] preparations. Among the humoral agents and electrolytes known to promote release of renin,[54] plasma epinephrine, arginine vasopressin, ACTH, sodium and potassium levels did not change in this study and thus probably did not contribute to the decline in PRA; however, local intrarenal effects cannot be excluded with certainty.

Norepinephrine and PRA levels decreased in this study despite the reductions in cardiac filling pressures, which are normally associated with increased levels of these hormones.[58,59] On the contrary, the decrease in plasma norepinephrine concentration correlated positively with the decline in right atrial pressure.

In the dog, release of vasopressin, like PRA, is inhibited by cardiopulmonary reflexes with vagal afferents.[60] However, digoxin in normal conscious dogs does not detectably suppress plasma arginine vasopressin, even when basal hormone levels are elevated by water restriction.[61] Moreover, vasopressin concentrations in normal human subjects are not affected by loading of cardiopulmonary or sinoaortic baroreceptors.[62] Responses of vasopressin to digitalis therapy in patients with CHF have not previously been reported. In the present study, neither arginine vasopressin nor plasma osmolality changed significantly after digoxin.

It is interesting that total SVR did not decrease in our patients despite significant reductions in PRA and plasma norepinephrine levels. The PRA findings appear to be consistent with those of previous investigations showing a poor correlation between PRA and hemodynamic variables in patients with CHF.[28,32] The norepinephrine result was unexpected, however, given the reported correlation between plasma norepinephrine levels and total SVR in patients in the baseline state.[28] In this study, the vasodilation anticipated from reduced plasma norepinephrine levels may have been blocked by the constrictive action of the digoxin itself. On the other hand, alternative mechanisms are suggested by the study of Schwartz et al,[63] who found no change in vascular resistance in patients with CHF when plasma norepinephrine levels were lowered by direct pharmacologic inhibition of catecholamine synthesis. Failure of resistance to decline in both experimental situations might be explained either by inability of the arterioles in patients with CHF to dilate normally in response to withdrawal of sympathetic tone (as has been shown with a variety of vasodilator stimuli[64]) or by the existence of other influences (possibly neurohumoral in nature) which exert a constrictive effect equal in magnitude to the potential vasodilation. Candidates for the latter role include reductions in the vasoactive kinins[65] or alterations in prostaglandins,[66] but these possibilities have not been evaluated.

In this study, cardiac output increased even though total SVR remained constant and both heart rate and pulmonary wedge pressure decreased. Accordingly, digoxin appears to have had a potent inotropic effect in these patients with CHF. This conclusion is strengthened by the observation that plasma norepinephrine levels declined, since sympathetic inhibition can be presumed to, if anything, further erode the strength of contraction of the failing myocardium. In studies reporting a decrease in SVR in patients taking digitalis, augmentation of cardiac output has been, in all cases, greater than that recorded here. However, it is unclear whether such increases are mainly the result of the direct effect of digitalis on the heart or of afterload reduction due to reflex-dilating actions on the peripheral vasculature. Because total SVR did not decline in the present investigation, the improvement in ventricular function with digoxin that we observed appears to have been entirely a result of enhancement of myocardial contractility.

Acknowledgment: We are grateful to Gary L. Robertson, MD, for the arginine vasopressin assays; to Thomas P. Gibson, MD, for the digoxin assays; to Craig F. Ansley, PhD, for statistical analysis of the data; to Mark Zucker, MD, Diane R. Talentowski, RN, Reneta Stadnicki, RN, Christine Stasior, RN, Coral A. Cawthorn, Paula Shanks and Grace H. Tomasa for technical assistance; to Joan Talano for the artwork; and

Response to the Valsalva Maneuver After the Fontan Procedure for Tricuspid Valve Atresia, Single Ventricle or Pulmonic Valve Atresia

SAMUEL S. GIDDING, MD, AMNON ROSENTHAL, MD,
ALBERT P. ROCCHINI, MD, and MACDONALD DICK, MD

The Valsalva maneuver was performed during cardiac catheterization in 9 patients who had undergone a Fontan operation (Fontan group) and in 10 control subjects. The Fontan group had higher right atrial (RA) pressure (16 ± 1 vs 4 ± 0.5 mm Hg, p <0.001), lower cardiac index (2.5 ± 0.1 vs 3.7 ± 0.2 liters/min/m^2, p <0.05), lower stroke index (32 ± 2 vs 44 ± 2 ml/beat/m^2, p <0.05), and higher systemic vascular resistance (31 ± 1 vs 24 ± 1 units, p <0.05) than the control group. Four patients in the Fontan group had a normal 4-phase Valsalva response, and 5 did not (p <0.05). RA pressure was similar in those who responded normally and those who did not (16 ± 0.5 vs 17 ± 1 mm Hg), whereas in those who responded normally cardiac index was higher (2.9 ± 0.2 vs 2.2 ± 0.1 liters/min/m^2, p <0.05), stroke index was higher (36 ± 1 vs 28 ± 1 ml/beat/m^2, p <0.05), and systemic vascular resistance was lower (28 ± 1 vs 31 ± 1, p <0.05). It is concluded that cardiac output is a better predictor of a normal response to the Valsalva maneuver than RA pressure in patients after the Fontan procedure. A normal response to the supine Valsalva maneuver suggests a cardiac index greater than 2.4 liters/min/m^2 and stroke index greater than 31 ml/beat/m^2. (Am J Cardiol 1985;56:905–909)

The Valsalva maneuver—maximal expiration against a closed glottis—is considered an excellent physiologic test for congestive heart failure.[1–4] During the maneuver, systemic venous return is obstructed, cardiac output decreases, and a reflex increase in systemic vascular resistance and heart rate occur. After release of strain, cardiac output increases and a characteristic overshoot in aortic pressure and pulse pressure occurs, as does reflex bradycardia. In patients with congestive heart failure, systemic venous return is not effectively diminished and a "square-wave response" with absence of the overshoot is observed (Fig. 1).

Elevated right atrial (RA) pressure and low cardiac output have been associated with an abnormal response to the maneuver.[1–3,5,6] Patients who have undergone the Fontan operation for repair of congenital heart disease (direct RA-to-pulmonary trunk or RA-to-right ventricle communications) usually have elevated RA pressure or low cardiac index as sequelae of the operation.[7–10] We performed the Valsalva maneuver in patients who had undergone successful repair by Fontan operation to determine if a normal aortic pressure response to the Valsalva maneuver is present, and if so, whether the patient's RA pressure or cardiac output are a better determinant of the normal response.

Methods

The Valsalva maneuver was performed in 19 patients during routine diagnostic cardiac catheterization. A Fontan or modified Fontan operation was performed in 9 patients (6 for tricuspid atresia, 2 for single ventricle and 1 for pulmonary atresia with intact ventricular septum). Ten patients served as control subjects. Mild congenital heart disease was present in 5 (mild aortic stenosis in 2 and mild pulmonic stenosis, mitral valve prolapse and cervical aortic arch in 1 patient each) and 5 were undergoing electrophysiologic study for localization of an accessory bypass tract. The mean age of patients with a Fontan operation was 15 ± 2 years and that of control subjects was 15 ± 1 years. The mean interval between operation and cardiac catheterization in the Fontan group was 3 ± 1 years. The operation performed was RA-to-pulmonary artery anastomosis in 7 patients, RA to right ventricular anastomosis in 1 patient and RA to pulmonary artery valved

TABLE I Hemodynamic Values at Rest in the Fontan Group and the Control Group

	Fontan Group (n = 9)	Control Group (n = 10)	p Value
Change in PAP, end strain (phase II to phase III) (mm Hg)	46 ± 7.0	36 ± 4.0	NS
Mean RAP (mm Hg)	16 ± 1	4 ± 0.5	<0.001
Cardiac index (liters/min/m^2)	2.5 ± 0.1	3.7 ± 0.2	<0.05
Stroke index (ml/beat/m^2)	32 ± 2	44 ± 2	<0.05
SVR (Wood units)	31 ± 1	24 ± 1	<0.05

NS = not significant; PAP = pulmonary artery pressure; RAP = right atrial pressure; SVR = systemic vascular resistance.

conduit in 1. This latter conduit was stenotic (15-mm Hg mean gradient) at the time of catheterization. In the Fontan group, 3 patients were in New York Heart Association (NYHA) functional classification class I, 3 were in class II and 3 were in class III. All control patients were class I.

All patients were supine. In each patient resting values of heart rate (average of 3 RR intervals), aortic pressure, RA pressure, pulmonary artery pressure and left ventricular end-diastolic pressure were simultaneously measured. Cardiac output was determined by thermodilution and indexed to body surface area. Stroke index and systemic vascular resistance were calculated. In 7 patients in the Fontan group left ventricular ejection fraction was determined from the left ventricular cineangiograms using Simpson's rule.

To perform the Valsalva maneuver each patient was asked to place his thumb in his mouth and expire maximally without allowing any air to escape. The maneuver was sustained until the characteristic rise and plateau in aortic diastolic pressure was observed, indicating an increase in peripheral resistance. Total duration of effort was between 10 and 15 seconds. Heart rate, aortic pressure and pulmonary artery pressure were recorded throughout the effort and for 20 cardiac cycles thereafter. Effort was assessed by measuring the decline in pulmonary artery systolic pressure (or a-wave) at the release of strain. This decrease was considered to reflect transthoracic pressure induced by the strain since there is no significant change in cardiac output at the transition from end strain (phase II) to release (phase III).[11,12] A difference of more than 20 mm Hg indicated a satisfactory effort (Table I). The response to the Valsalva maneuver was quantitated by assessing changes in aortic systolic pressure, aortic pulse pressure and heart rate during the maneuver (Fig. 2). For each variable, the difference from values at rest was determined at the release of strain (phase III) and at the peak pulse pressure during the overshoot (phase IV). The number of beats from release of the strain to peak pulse pressure was calculated for each patient with a normal response curve. A normal response curve was defined as having all 4 phases of the characteristic response present for each variable (systolic pressure, pulse pressure and heart rate). All other responses were classified as abnormal.

Within each group, mean and standard error of the mean were calculated for each variable at rest. The Fontan group was further subdivided into normal and abnormal responders. Group comparisons were made using the unpaired t test. A level of 0.05 was selected as the criterion for significance of a positive result.

Results

Hemodynamic values measured at rest are presented in Table I. The Fontan group has significantly higher mean RA pressure, lower cardiac index, lower stroke index and higher systemic vascular resistance than the control group. Systolic blood pressure at rest (114 ± 3

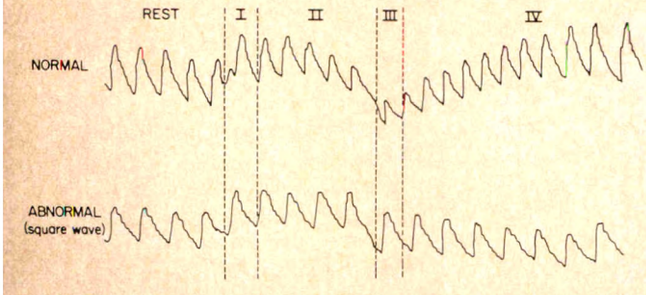

FIGURE 1. Normal and abnormal aortic pressure responses to the Valsalva maneuver in patients after Fontan operation. Phase I represents the onset of strain. Phase II, which has been shortened, represents the maintenance of strain. Phase III is the release of the strain. Phase IV is referred to as the overshoot period. In the normal response during phase I, there is an immediate increase in systolic blood pressure, corresponding to the increase in transthoracic pressure. In phase II, systemic venous return is obstructed by the increased transthoracic pressure. As a result, systolic blood pressure and pulse pressure fall. Heart rate and systemic resistance increase as cardiac output decreases. During phase III, systolic pressure decreases well below values at rest, reflecting the decrease in transthoracic pressure and cardiac output. Pulse pressure remains low and tachycardia persists. In phase IV, systemic venous return and cardiac output rapidly increase, causing an increase in systolic pressure and pulse pressure. These pressures increase above values at rest because of the increased systemic resistance and produce a reflex bradycardia. In the patient with congestive heart failure, the obstruction to venous return does not alter cardiac performance. Therefore, pulse pressure and heart rate remain constant during phase II, and return to baseline values at end strain, giving the characteristic "square-wave" appearance to the response curve.

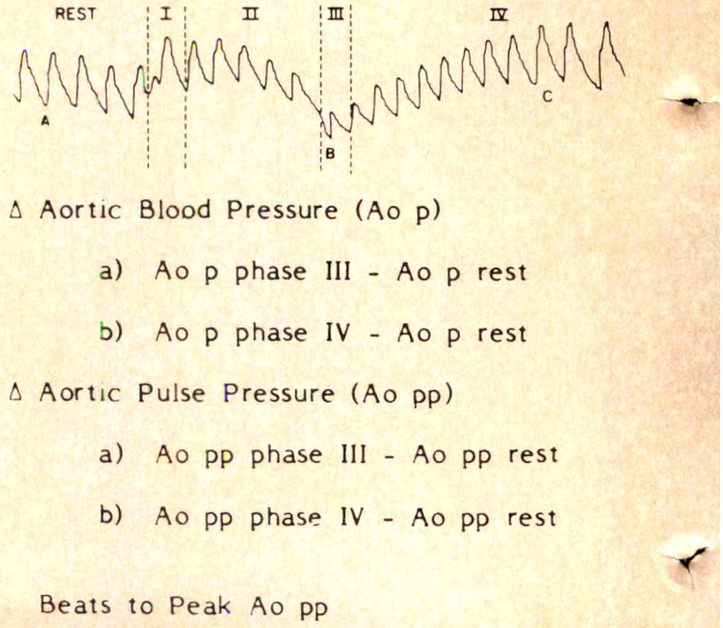

FIGURE 2. Calculation used to quantitate the shape of the Valsalva response curve. **A, B** and **C** demonstrate the beats selected to make measurements of systolic pressure, pulse pressure and beats to peak pulse pressure respectively. Heart rate was calculated as the average of 3 RR intervals before strain, at phase III, and during reflex bradycardia.

vs 119 ± 3 mm Hg), pulse pressure (34 ± 3 vs 37 ± 2 mm Hg) and heart rate (78 ± 5 vs 86 ± 4 beats/min) were similar in both groups. Whereas all 10 control patients had a normal 4-phase response to the maneuver, 4 Fontan patients had a normal response and 5 had an abnormal response (Fig. 3). At end strain (phase III), patients in both control and Fontan groups with a normal response had a similar decrease in systolic pressure (40 ± 5 vs 37 ± 9 mm Hg), decrease in pulse pressure (18 ± 2 vs 25 ± 4 mm Hg), and increase in heart rate (29 ± 4 vs 20 ± 4 beats/min) (differences not significant [NS]). During the overshoot (phase IV) these groups had similar (NS) increases in systolic pressure (27 ± 4 vs 30 ± 4 mm Hg), and pulse pressure (17 ± 3 vs 20 ± 2 mm Hg); reflex bradycardia (−21 ± 3 vs −21 ± 4 beats/min). However, the number of beats to peak pulse pressure during the overshoot was significantly lower in the control group (9 ± 1 vs 12 ± 1 beats, $p < 0.05$), suggesting delayed transmission of the systemic venous return to the left heart in the Fontan group.

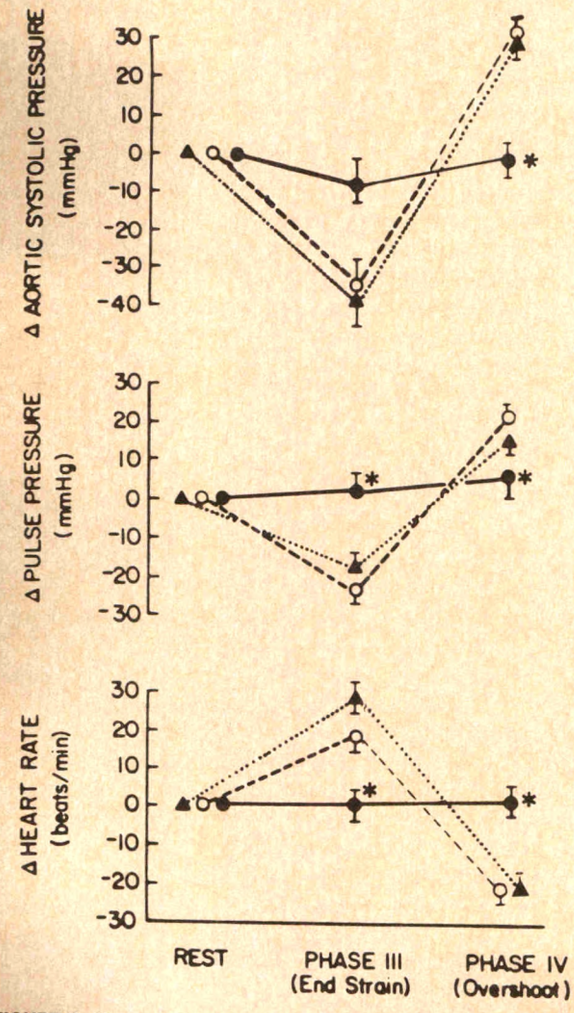

FIGURE 3. Change from values in response to the Valsalva maneuver in 3 groups: control patients (**triangles**), Fontan patients with a normal qualitative response (**circles**) and Fontan patients with an abnormal response (**dots**). Statistical differences (*$p < 0.05$, Fontan abnormal response group vs control group) were found between the control group and the group with an abnormal response in aortic systolic pressure, pulse pressure and heart rate at end strain and during the overshoot.

The 5 patients in the Fontan group with an abnormal Valsalva response had no significant change from rest values to the release of strain or during the overshoot in systolic pressure (−6 ± 8 mm Hg, end strain; −2 ± 4 mm Hg, overshoot), pulse pressure (1 ± 6 mm Hg, end strain; 5 ± 2 mm Hg, overshoot), or heart rate (2 ± 3 beats/min, end strain; 3 ± 2 beats/min, overshoot). Compared with patients in the control group, patients in the Fontan group with an abnormal response had statistically different systolic pressure, pulse pressure and heart rate responses at end strain and during the overshoot (Fig. 3).

Figure 4 is a comparison of RA pressure, cardiac index, stroke index and systemic vascular resistance between the 2 Fontan groups. RA pressure did not differ significantly between the 2 groups (16 ± 0.5 vs 17 ± 1 mm Hg); however, those with a normal response had a higher mean cardiac index (2.9 ± 0.2 vs 2.2 ± 0.1 liters/min/m^2, $p < 0.05$) and higher stroke index (36 ± 1 vs 28 ± 1 ml/beat/m^2, $p < 0.05$). A cardiac index of 2.4 liters/min/m^2 or less and a stroke index less than 31 ml/beat/m^2 were associated with an abnormal Valsalva response. Systemic vascular resistance was also significantly lower in the normal response group (28 ± 1 vs 31 ± 1 units, $p < 0.05$). In both groups mean left ventricular end-diastolic pressure was 8 ± 1 mm Hg. Among the 7 patients with Fontan operation in whom an ejection fraction was measured, the 3 patients with the highest ejection fractions (70%, 76% and 78%) had a normal response to Valsalva maneuver and 4 (range 31 to 61%) had an abnormal response. Three of the 4 patients with a normal response were in NYHA functional classification I and 1 patient was in class II. All patients who

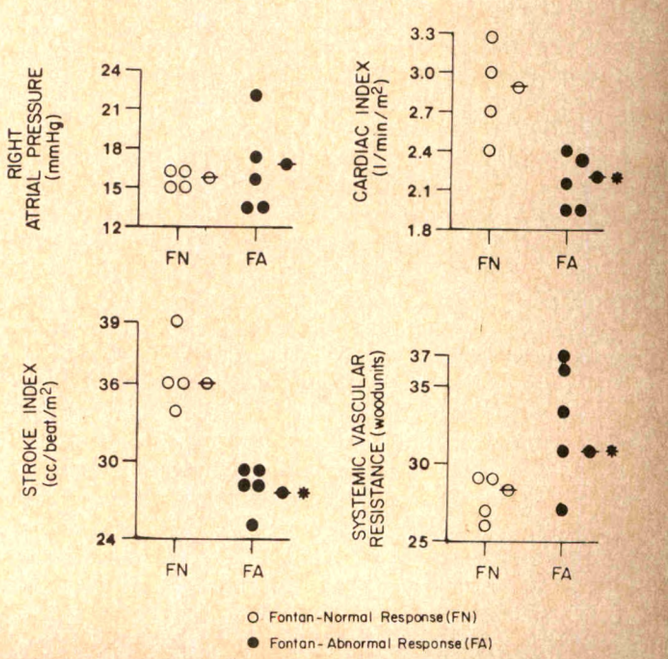

FIGURE 4. Hemodynamic measurements at rest in Fontan patients with a normal response to the Valsalva maneuver (**circles**) and those with an abnormal response (**dots**). **Crossed symbols** represent mean values. Right atrial pressure was similar in both groups. However, cardiac index and stroke index were statistically higher and systemic vascular resistance was lower (*$p < 0.05$) in the normal response group.

responded abnormally were in functional class II or greater. Thus, in our patients who have undergone a Fontan operation, response to the Valsalva maneuver is independent of RA pressure and appears to be related to cardiac performance as reflected by assessment of cardiac output, stroke volume, ejection fraction and NYHA functional classification.

Discussion

The Valsalva maneuver initiates a complex sequence of hemodynamic and reflex responses in the normal[13] subject (Fig. 1) and fails to initiate this sequence in the patient with congestive heart failure because systemic venous return is not sufficiently obstructed during the maneuver.[3,5,11,12] The characteristic fall in systolic pressure and pulse pressure below baseline at the release of strain, subsequent overshoot of systolic pressure and pulse pressure, and reflex heart rate responses are absent in the latter group. Several studies indicate that elevated RA pressure and right ventricular dysfunction cause an abnormal response to the Valsalva maneuver. An abnormal response has been found in patients with right ventricular failure secondary to cor pulmonale or pulmonic stenosis.[1–3] Judson et al[2] correlated the presence of an abnormal response with elevation of right ventricular end-diastolic pressure and speculated that patients with left-sided heart failure or left-sided obstruction would not develop an abnormal response unless elevations of right ventricular end-diastolic pressure were also present. By producing an acute volume load in patients with a normal response and thus increasing RA pressure, Judson changed the response to a "square wave." Conversely, maneuvers that diminished RA pressure, such as venesection or the placement of thigh cuffs altered abnormal responses to normal. O'Neill and Cudkowicz[6] studied patients with normal and abnormal responses to Valsalva maneuver and demonstrated elevated RA pressures (mean 16 mm Hg) in patients with an abnormal response. Wilkinson et al[5] performed Valsalva-like maneuvers in anesthetized dogs and studied the effects of changes in blood volume and RA pressure. They concluded that an abnormal response could be induced by increasing central blood volume. Elevation of RA pressure produced by the increased blood volume increased effective RA pressure (RA pressure − transthoracic pressure), prevented obstruction of venous return, and thus caused an abnormal response to the maneuver.

Because patients who have undergone a Fontan operation have elevated RA pressures[7–10,14–16] and either lack or have a poorly functioning right ventricular pump, the above clinical and experimental studies would suggest that patients should have an abnormal response to the Valsalva maneuver after they undergo the Fontan procedure. Why, then, did 4 of our 9 patients have a normal response? The data suggest that the most important determinant is left ventricular performance. The Fontan operation establishes an essentially passive channel between the systemic venous return and the pulmonary circulation. Pulmonary flow and RA pressure are, in large measure, dependent on left ventricular end-diastolic pressure, resistance of the pulmonary circulation and resistance of the conduit. RA pressure under these circumstances is expected to be elevated because it will reflect the total resistance to flow. Our patients with elevated RA pressure but higher cardiac index, stroke index, and left ventricular ejection fraction had normal responses to the Valsalva maneuver. We postulate that in those patients, the left ventricle drains the pulmonary vasculature during the strain. Effective RA pressure is sufficiently low to obstruct venous return and remains low because of an effective left ventricular pump. When strain is released, the dammed venous return is transmitted to the left side of the heart, producing overshoot. Patients with low cardiac index because of left ventricular dysfunction will not have low effective RA pressures at the onset of strain and will not effectively drain their pulmonary circulation during the strain. Systemic venous return will not be occluded and cardiac output will remain unchanged, thus producing a "square-wave response."

Patients with right ventricular failure secondary to cor pulmonale or pulmonic stenosis have elevated RA pressures because of obstruction to pulmonary flow, poor right ventricular compliance and increased blood volume in the venous capacitance vessels.[17] These factors contribute to maintaining a higher effective RA pressure during the Valsalva strain, failure to diminish venous return, and the subsequent abnormal response.[2,5] Indeed, in 1 of our patients with an obstructed conduit, obstruction contributed to a low cardiac index and an abnormal Valsalva response.

Patients who responded abnormally after the Fontan operation had poorer cardiac function as assessed by cardiac index, stroke index and ejection fraction, but their left ventricular end-diastolic pressures were similar to those of the patients who responded normally and were within the normal range of values. This similar left ventricular end-diastolic pressure value accounts for the similarity in RA pressure between groups (the only exception being that patient with an obstructed valved conduit and RA pressure of 22 mm Hg). The explanation for the similarity in pressures, despite marked differences in measured overall cardiac performance, may relate to the difference in the determinants of left ventricular preload in Fontan patients compared with patients with structurally normal hearts. In the structurally normal heart, left ventricular failure results in pulmonary congestion, elevation of pulmonary venous pressure and, when severe, right ventricular failure. In patients who have undergone the Fontan operation, and have direct RA to pulmonary artery continuity, there is no pulmonary valve and no effective right ventricular pump. When the left ventricle fails, it has not only the pulmonary circulation, but the whole venous capacitance as a reservoir. Thus, a much larger increase in blood volume may be necessary to increase left ventricular end-diastolic pressure in patients who undergo the Fontan procedure.[18]

VENTRICULAR REMODELING IN MYOCARDIAL INFARCTION—THE RAT AND THE HUMAN

The excellent analysis by Roberts et al[1] of left ventricular (LV) remodeling in a rat infarct model makes several observations that should be related to LV remodeling in the human after acute myocardial infarction. Infarct expansion is defined as stretching and thinning of the infarct zone after AMI and it leads to LV dilatation and distortion.[2] Data of Roberts et al[3] show that any increase in LV cavity size in the rat 2 days after AMI is due to tissue resorption in the infarct zone, inasmuch as there is no increase in the outer LV dimensions at that time; i.e. there is no increase in infarct segment length. In contrast, our 2-D echocardiographic (echo) studies in humans have shown dramatic increases of infarct segment length up to twice normal within the first 24 hours and as soon as 90 minutes of the onset of chest discomfort, before inflammation or tissue resorption has begun.[4] In humans, marked increases in radiographic cardiac sillhouette size in the early hours of AMI also speak for an increase in external heart size, which in our 2-D echo studies is primarily due to infarct expansion rather than the Starling effect.[4,5]

Infarct zone scar contraction over several weeks in the infarct segment, reported in the study of Roberts et al, is consistent with similar findings by Theroux et al[6] in the canine infarct model. We observed a similar tendency in the infarct zone in our long-term 2-D echo studies of infarct patients, but only in those *without* infarct expansion.[7] In patients *with* infarct expansion, the infarct segment tended to *increase* in length over a mean 13-month follow-up. "Compensatory" lengthening of the noninfarcted segment over 3 weeks was seen in Roberts' study, an observation we also made in patients with infarct expansion in long-term follow-up.[7]

The data in this article also show the independence of LV wall thinning and infarct expansion, terms that have sometimes been used interchangeably. These 2 phenomena are functionally related to each other only in the first hours of AMI, when stretching of myocardium necessarily leads to a decrease in wall thickness. However, the tissue resorption and scar replacement of necrotic myocardium come under the influence of the multifactorial processes of healing, which may well lead to variability of wall thickness independent of the degree or even the presence of infarct expansion as shown in this study.

In summary, there appear to be major differences in the topographic behavior of the rat heart after AMI compared to the human. Although studies such as this help to focus attention on the importance of infarct-associated topographic changes, they point out that models more closely mimicking the human infarct are needed.

SYSTOLIC TIME INTERVALS IN CORONARY HEART DISEASE AT REST AND DURING EXERCISE

Vanhees et al[1] present interesting and practical conclusions on the effect of β-adrenoceptor blockade on physical training and exercise. I was surprised, however, at some important details of the protocol as published. I have no quarrel with their conclusions regarding the effect of β-adrenoceptor blockade. Can they clarify the following: (1) It appears that all 28 patients both achieved exercise at 110 W and had adequate recording of systolic time intervals (STI) by ordinary methods (i.e., methods virtually immune to motion artifact like the ear densitogram[2] were not used). They do not specify whether a funnel, a balloon or a pressure sensitive device was positioned over the carotid artery. With these "standard" pickups, it is common, as with PCG microphones, for many exercising patients to produce considerable artifact.[3] It is thus surprising that satisfactory data could be obtained from all 28 patients. (2) The investigators analyzed only 3 consecutive beats (usually 10 or even 5 consecutive beats are averaged for STI). Perhaps this was because of technical beat-to-beat variation due to motion artifacts, but this would not permit averaging over the respiratory phases, and respiratory effects during exercise are exaggerated. Were the patients recorded during voluntary apnea? (3) The preejection period (PEP) is described as significantly affected by heart rate (HR). However, it has been shown repeatedly[4] that direct HR effect is unlikely, and that PEP and HR are individually under the influence of sympathetic tone at rest and sympathetic stimulation during exercise. They further indicate that they used PEPc, because they were attempting to allow for HR[4]. They discuss "PEPc" referring to Table VI. However, Table VI mentions PEP, not PEPc in its title. If this, in fact, is PEPc, it would be possible to extract PEP by considering the HR. For example, a rough estimation from Figure 1 for HR at 110 W gives the following approximate HR: no β blockade—before training, 131 beats/min; after training, 111 beats/min; with β blockade—before training, 112 beats/min; after training, 103 beats/min. If we then arbitrarily apply Weissler's slope factor for PEP vs HR, 0.4, we can recalculate the uncorrected PEP as 48, 28, 33 and 47 ms, respectively. (These will be wrong if Vanhees et al used a different "correction"—but directionally correct). These PEP results indicate much greater relative changes than are shown in the table and may be highly significant for the difference between treatment groups. The text is unclear as to whether Table VI is really PEP or PEPc. Furthermore, in any article on STI the actual HR at every point should be given.

These comments are made not so much in direct criticism of an otherwise excellent work, but rather in search of clarification.

REPLY: In response to the letter of Spodick, the following may clarify the various problems raised: (1) The carotid pulse was obtained by a funnel device (pulse transducer Siemens 860-2). During exercise it was attempted to position the device so that adequate recordings were obtained, which, at the pretraining evaluation, was successful in 39 patients. Of these, 11 were lost to study for problems not related to methodology. We failed, however, to register adequate pretraining data at exercise in 9 other patients, who were therefore excluded from further study. (2) The recordings were made at end-expiration during brief periods of voluntary apnea, both before and after training. We agree that adequate recordings would not be possible at exercise throughout respiration. The variation in 3 consecutive beats recorded in held respiration during exercise is sufficiently small so that the average of 3 beats is adequate. (3) For comparison of STI before and after training, analysis of covariance was applied. For PEP at rest in the recumbent

* Letters (from the United States) concerning a particular article in the *Journal* must be received within 2 months of the article's publication, and should be limited (with rare exceptions) to 2 double-spaced typewritten pages. Two copies must be submitted.

position, HR was not a significant covariate, which is in agreement with the data of Spodick and others. At exercise, however, HR was a significant covariate for PEP, so that the correction of PEP for HR was considered mandatory. (4) All reported STI in tables and figures are measured STI. The statistical comparisons were made on the basis of analysis of covariance; since HR was a significant covariate for left ventricular ejection time (LVET) and PEP during exercise, the F values for the effect of training are based on $LVET_c$ and PEP_c (i.e. taking HR into account).

BALLOON DILATATION CATHETER SIZE SELECTION

I read the recently published Proceedings of the National Heart, Lung, and Blood Institute (NHLBI) Workshop on the Outcome of Percutaneous Transluminal Coronary Angioplasty (PTCA).[1] In that review, Cowley et al reported that coronary arterial dissection is more frequent in women, in dilatations of the right coronary artery, in patients with more advanced multivessel disease, or in vessels with tubular, nondiscrete or eccentric lesions.[2] I question whether some of these may not have been patients in whom coronary diameter was smaller. I am writing in hopes of stimulating more discussion of the choice of balloon dilatation catheter size. Previous experience in our laboratory was patterned after that reported by Gruentzig and Meier[3] in the same workshop with "almost all" cases being done with 3.0-mm outer diameter balloon catheters and 2.0-, 2.5- and 3.7-mm sizes being used for special situations only. More recently, however, I have considered that coronary dissection should be more frequent if overdilatation is performed. Consequently, I have recently been trying to match more objectively the balloon catheter size to the desired lumen diameter. This was first done using measurements from calibrated 105-mm films and a 5-inch image intensifier. Equally accurate selections can be made, however, simply by comparison of desired lumen size to the diameter of arteriographic catheters on cineangiograms. The 1/3-mm and French size relation is useful to remember: *French size:* 6, 7.5, 8, 9, 10.5, 11.1; *diameter in mm:* 2.0, 2.5, 2.67, 3.0, 3.5, 3.7. If this were used in selecting a dilatation catheter, the 3.0-mm balloon would be chosen when the desired arterial diameter was equal to the diameter of a 9Fr guiding catheter.

I suspect that established investigators (such as those who participated in the NHLBI Workshop), from experience, can make the catheter selection accurately without such a formal comparison. Angiographers who perform angioplasty less often may find it helpful. I would appreciate the comments of other investigators as to whether they believe individualization of the balloon size is likely to be helpful. In addition, it would be interesting if one of the major centers performing angioplasty would conduct a retrospective review in which balloon dilatation catheter size was converted to a percentage of optimal arterial luminal diameter. A comparison of a group of patients with long-term good result, a group with restenosis, and a group with arterial dissection may be able to establish whether relative balloon size is a factor in either dissection or restenosis.

Edwin W. Rogers, MD

REPLY: The selection of balloon dilatation catheters to more closely approximate the size of smaller arteries may reduce the risk of coronary dissection but may also have an adverse effect on lesion recurrence rates. Data from this institution,[1,2] however, suggest that coronary dissection is largely a function of lesion morphology and agrees with the findings of the NHLBI Registry (Ref. 2 above).

Higher inflation pressure, which in part influences balloon diameter, is a major determinant of expansile stress within the artery. A modest increase in balloon inflation pressure does not increase the incidence of acute complications or dissection but improves the immediate haemodynamic results and may have had a favorable effect on lesion recurrence.[3] More recent data confirmed the importance of a satisfactory final transstenotic gradient in reducing the recurrence rate.[4,5] Whether this is best achieved by longer balloon inflations, higher inflation pressures or larger balloon sizes is unknown.

Preliminary reports from other centers have suggested that a larger balloon diameter/arterial diameter ratio does not increase the risk of dissection[6,7] but may significantly reduce recurrence rate.[7] We are currently undertaking a study examining the influence of balloon size on acute complication and recurrence rates. However, more severe degrees of intimal dissection are certainly associated with increased risk of acute closure and emergency coronary surgery.[8] Until definitive results are available, it would be prudent to carefully match balloon size to arterial lumen diameter, remaining on the smaller side of the scale. Our approach has been to do this by referring to the known diameter of the 8Fr or 9Fr guiding catheters. In practice this usually results in choosing a 3.0-mm balloon while occasionally using balloons of 2.5 mm or 3.7 mm in diameter (Ref. 1 above).

REPLY: Rogers' questions and comments regarding dilatation catheter size selection are useful. Concerning factors associated with a higher frequency of dissection in the NHLBI PTCA Registry, the incidence of either intimal tear (not a complication) or coronary dissection (a complication) was significantly higher in women, with PTCA of the right coronary artery, in patients with multivessel disease, and in those with tubular, nondiscrete, or eccentric lesions (Ref. 2 in Rogers' letter). It is likely that the higher incidence in women was related to smaller vessel size. Although data on vessel size are not available in the registry, body size has been shown to correlate with coronary artery size[1] and women in the registry were significantly smaller than men (mean body surface area: 1.70 vs 1.96, $p < 0.001$). Despite these size differences, a 3.0-mm balloon was the smallest one available during most of the registry experience and was used in most men and women. A relation between vessel size and the higher incidence of tear/dissection with right coronary artery PTCA, multivessel disease and specific lesion morphology is not evident from the registry data.

The question of appropriate matching of balloon size and vessel size addresses an important issue in view of the variety of balloon sizes currently available and the expanded application of coronary angioplasty to smaller vessels and more distal lesions. Individualization of balloon size selection is a sound approach that should be strongly recommended. It is likely that the risk of major plaque disruption and occlusive dissection is higher with overdilatation, and proper balloon/vessel sizing should reduce the occurrence of overinflation. However, precise determination of vessel size is confounded by the substantial degree of physiologic vasoreactivity of the coronary vasculature. These vessels are frequently significantly larger in caliber at the time of angioplasty compared with their size at diagnostic angiography, which is likely due to the liberal vasodilator therapy administered in conjunction with PTCA. Estimation of vessel size, therefore, will often represent only a rough approxi-

mation of vessel caliber and may underestimate lumen diameter at the time of dilatation. In addition, balloon size frequently increases beyond the specified predetermined diameter at high inflation pressures due to the compliance characteristics of the balloon material, so that overdistention may occur at high pressures despite appropriate balloon size selection. With these qualifications in mind, it is nevertheless desirable to individualize balloon size selection to approximate an optimal inflation diameter for each vessel segment to be dilated. The method of sizing using angiographic catheter French size suggested by Rogers provides a simple and practical approach for balloon catheter selection.

The potential role of relative balloon size to optimal arterial lumen diameter as a determinant of either dissection or restenosis should be carefully evaluated. Although overdilatation may be associated with an increased risk of dissection, the incidence of restenosis appears to be lower when a more complete dilatation is achieved. This is suggested from the registry report on restenosis, which demonstrated a significant relation between the residual gradient after PTCA and the frequency of restenosis (Ref. 5 in Reply above). Evaluation of the effects of procedural factors such as relative balloon size, maximal inflation pressure, and duration of inflation on acute outcome and restenosis using currently available catheter systems is clearly needed and should be of considerable value toward further improving early and long-term results with coronary angioplasty.

SYMPATHETIC TONE IN CONGESTIVE HEART FAILURE

The study by Swedberg et al,[1] which attempted to assess myocardial catecholamine balance in patients with congestive heart failure (CHF), had major methodologic flaws. As Swedberg et al stated, the disposition of norepinephrine (NE) (after release) is complex, the spillover to plasma being determined by both neural release and neuronal and extraneuronal uptake. Their calculations did not take account of these factors. Because NE is both released to and extracted from plasma, a simple proportional decrement in concentration is not an acurate measure of extraction. The use by Swedberg et al of the Fick equation (uncorrected for NE extraction) to derive "NE release" was inappropriate for the same reason. Finally, the combination in their calculations of plasma catecholamine concentrations and whole blood rather than plasma flow was inappropriate.

Swedberg et al rejected the possibility that their results were influenced by the diuretic therapy of patients with CHF, because one-third of their control subjects were taking a diuretic drug. Most of the study group appeared to have taken a loop diuretic for CHF, whereas at least some of the control group took a thiazide diuretic for systemic hypertension. Diuretic therapy does increase NE turnover.[2] The possibility that therapy influences the results of Swedberg et al cannot be excluded.

An alternative method, which does account for both NE release and extraction, exists for the estimation of total and regional sympathetic tone.[3,4] A tracer infusion of ^{3}H-NE allows the calculation of release (R_{NE}) and clearance (C_{NE}) of NE:

$$R_{NE} = \frac{\text{rate of infusion (dpm/min)}}{\text{specific radioactivity of plasma (dpm/pg)}}$$

and

$$C_{NE} = \frac{\text{rate of infusion (dpm/min)}}{\text{plasma } ^3\text{H-NE concentration (dpm/ml)}}$$

Plasma flow is calculated from blood flow and the arterial hematocrit. Regional extraction of ^{3}H-NE (E_{TRIT}) is used to correct the Fick equation in the calculation of regional NE release: $Reg_{NE} = [(NE_V - NE_A) + NE_A \cdot E_{TRIT}] \times$ organ plasma flow. The methods have been used to evaluate sympathetic function in normal humans,[5] and in patients with essential hypertension,[4] thyroid disease,[5] autonomic insufficiency[2] and hepatic cirrhosis.[6] The effects of sympathetic and antidepressant drugs have been studied.[2,6]

It is appropriate and desirable that studies of regional sympathetic tone be performed in patients with CHF. However, it is essential that such invasive studies separate the effects of the disease from those of its treatment, and use a method that takes account of the bidirectional fluxes of NE in tissues.

REPLY: We greatly appreciate the criticisms and suggestions of Hasking, Esler and Jennings regarding our report on myocardial catecholamine balance in CHF. We are aware of alternative methods to assess total and regional sympathetic tone with the use of tracer infusion and completely agree that without the knowledge of neural release and neuronal and extraneuronal uptake, the significance of increased myocardial norepinephrine release in patients with CHF remains uncertain. We like to reemphasize that our study did not report the "disposition of norepinephrine after release" and this has been stated as Hasking et al noted. The catecholamines were assayed by radioenzymatic method, the validity of which is well known. The hematocrits in the 2 groups of patients were virtually identical. Thus, estimation of net myocardial NE release, by determining the coronary sinus blood flow, appears to be a valid technique.

Although it is known that diuretic therapy can influence catecholamine release, we did not find in our patients any differences in the catecholamine concentrations in relation to the diuretic therapy. Thus marked increase in NE concentration in coronary sinus venous blood and an approximately 20-fold increase in net myocardial NE release in patients with overt CHF cannot be explained by diuretic or any other prior pharmacologic intervention. We agree that without further studies, as suggested by Hasking et al, the significance of the enhanced myocardial NE release remains uncertain.

Clinical Echocardiography

Hemodynamic and Pathological Correlations

by José Missri, MD

0-914316-41-9, 282 pages, 173 illus., Oct. '84, $45.00

Dr. Missri has produced a unique contribution to the further understanding and application of Doppler echocardiography in the clinical practice of medicine. This book provides the reader with ready access to a body of knowledge so logically and clearly presented that its practical utility is undeniable. Enhanced by 139 halftones, 16 line drawings and 18 tables, the information contained within its concise 282 pages is easily absorbed. And the 315 references cited not only support the material presented but serve as an excellent guide to anyone interested in further in-depth reading.

NITROSTAT®
(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;
N 0071-0571-13—Convenience Package.

NATURE
HAS A WAY
OF PROTECTING
ITS OWN.

So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of label claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1]
NITROSTAT...useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept, Parke-Davis.

Foreword

During the last 20 years a very large number of studies have been published on the effects of β-adrenoceptor blocking agents in patients during and after myocardial infarction. According to a recent review,[1] there are at least 65 such trials including about 50,000 patients. In addition there are some studies in progress or not yet fully reported.

Prophylactic institution of β blockers after myocardial infarction is of proven value and the pooled results of all placebo-controlled trials show a very significant reduction of 25% in mortality at 1 to 2 years. A similar reduction was also obtained for reinfarctions. Most of the studies are of the late-entry type, with start of treatment 1 to 2 weeks after onset of infarction. The most convincing studies were the 3 large trials on timolol,[2] metoprolol[3] and propranolol[4] published in 1981; each showed a significant reduction in total mortality.

During the acute phase of myocardial infarction, mainly during the hospital stay, many studies have demonstrated favorable effects of β blockers on chest pain, infarct development, arrhythmias, hemodynamics and tolerance, but few have investigated mortality and morbidity. Only 1 study, The Göteborg Metoprolol Trial,[3] has shown positive effects on early mortality, and the effects were significant at 3 months. This trial also showed beneficial effects on all clinical variables studied.[5] Based on the results of this trial the MIAMI (Metoprolol in Acute Myocardial Infarction) Trial was designed to study further the effects of metoprolol therapy on mortality and morbidity during the first 15 days after onset of symptoms in patients with suspected myocardial infarction. The major results of this trial were recently published;[6] the present symposium proceedings are a comprehensive and final report on all findings during the 15-day trial period.

The MIAMI Trial was made possible by excellent collaborative work among committee members, investigators, doctors, nurses and other personnel in 104 hospitals in 17 countries. On behalf of the members of the Steering Committee, I express our sincere thanks for their cooperation.

Åke Hjalmarson
Chairman of the Steering Committee

Metoprolol in Acute Myocardial Infarction (MIAMI)

Introduction

The MIAMI Trial Research Group

In the Western world, coronary artery disease constitutes the single most common cause of death in middle-aged men and women. This remains so despite a recent decline in mortality from the disease in some countries, including the United States.[1] The mortality rate from acute myocardial infarction (AMI) during the hospital stay usually ranges between 10 and 20% in unselected groups of patients younger than 70 years of age.[2] The magnitude of the problem has led to the planning and realization of a number of trials aimed at assessing the effectiveness of various interventions to reduce mortality and new events. The first clinically useful β blocker, propranolol, became available in 1964. Shortly thereafter, Snow[3] published the results of an open study with propranolol in 93 patients after AMI, showing a significant reduction in mortality. Subsequently many trials have evaluated the effect of β blockade on survival, during both the acute stage of myocardial infarction and the long-term follow-up.[4–13]

The methodology of clinical trials has undergone considerable refinement during the last decade. An increasing number of well-controlled and organized trials have presented evidence that β blockade may reduce long-term mortality, sudden death or reinfarction in patients with myocardial infarction.

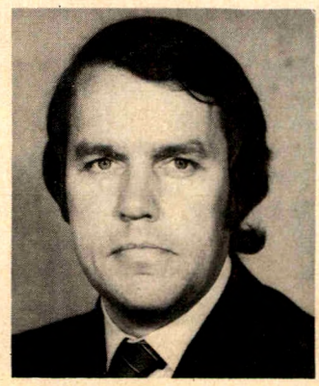
Since Snow's publication, several randomized, prospective, double-blind studies, each with more than 100 patients, have been performed and have not confirmed his findings regarding the early mortality reduction within a few weeks after onset of myocardial infarction.[14–20]

Only 2 placebo-controlled, early-entry studies with mortality reduction as a major objective have been published.[8,10] In these studies most patients were included within 12 hours after onset of symptoms indicating AMI. Neither study was able to show a significant reduction in the short-term mortality, i.e., within 2 to 3 weeks after onset of AMI, nor were they designed for this particular purpose. In the Copenhagen Alprenolol Study[8] the mortality was reduced only in patients younger than 65 years after 1 year of treatment. In the Göteborg Metoprolol Trial[10] a significant reduction in mortality was seen for all age groups after 3 months.

Early intravenous administration of metoprolol (within 12 hours) has been shown to favorably influence various indexes associated with infarct size.[21–23] Further, it has been shown to reduce ischemic chest pain,[24] need of analgesics[24] and signs of impaired left ventricular function.[25] The finding of a shorter hospital stay might be explained by these effects.[21] Another important action of metoprolol appears to be a marked reduction of serious ventricular arrhythmias.[26] Some of these findings have been reported with other β blockers.[27–30].

At the time of planning the present study the question of whether it was possible to markedly reduce the short-term mortality, e.g., during the first 2 weeks (essentially the hospital period) remained unanswered.

In a subgroup of patients from the Göteborg Metoprolol Trial, all of whom had an entry heart rate $\geq$70 beats/min, systolic blood pressure $\geq$110 mm Hg and no earlier β-blockade therapy, there was a 45% reduction in mortality as early as 15 days after inclusion, from 7.0% in the placebo group to 3.8% in the metoprolol group. The number of such patients, however, was



Åke Hjalmarson, MD, PhD
Chairman, Steering Committee, MIAMI Trial Research Group

too small for that study to provide conclusive results, and the findings were from retrospectively designed analyses.

Based on the experience from the previous Göteborg Metoprolol Trial,[10] a new study involving a larger group of patients was necessary to answer conclusively the question of whether it was possible to reduce the short-term mortality during the hospital period in AMI patients. This trial was named "Metoprolol in Acute Myocardial Infarction" (MIAMI). The patients were allowed to enter if they were not undergoing treatment with β blockers, had a heart rate >65 beats/min and a systolic blood pressure >105 mm Hg. In order to particularly demonstrate the effects of metoprolol during the early phase, variables other than death were investigated.

It should be stressed that these patients could not be expected to be representative of the entire myocardial infarction population generally seen in coronary care units. It might also be expected that correlations between some variables (e.g., heart rate and blood pressure) and outcomes reported in other studies might be distorted or not demonstrable because of this selection.

With this background and previous experience, particularly the Göteborg Metoprolol Trial,[10] the following primary and secondary objectives were selected.

The primary objective was to evaluate whether metoprolol could reduce the mortality from all causes over the period of 15 days (the trial period) in patients hospitalized with a suspected or definite AMI.

The secondary objectives were to assess the effect of metoprolol on the sum of both deaths and patients with nonfatal ventricular fibrillation (VF) during the first 5 days; enzyme-related infarct size within 3 days (days 0 to 3); incidence of definite AMI within 3 days (days 0 to 3); incidence of late first infarctions during the trial period (days 4 to 15); incidence of recurrent infarctions during the trial period (days 4 to 15); incidence of definite AMI during the trial period (5 and 15 days) in patients with and without electrocardiographic signs of infarction on admission; incidence of VF (nonfatal and fatal, number of patients and episodes) and presence of left ventricular heart failure/congestive heart failure (number of patients and use of diuretics) and chest pain (pain duration and use of analgesics) during 5 days and 15 days; and tolerance, safety and adverse events during 5 days and 15 days.

Further, a number of retrospective analyses were made to determine whether the effect of metoprolol was related to entry heart rate, site of suspected infarction and interval between onset of symptoms and start of treatment (subgroup hypotheses).

Some of the main findings of the MIAMI trial have been published previously.[31] This *American Journal of Cardiology* supplement is intended to provide a detailed reporting of the results relating to the basic protocol.

Patients and Methods

The MIAMI Trial Research Group

The effects of early intervention with metoprolol in patients with suspected or definite acute myocardial infarction (AMI) have been assessed in a randomized, double-blind, placebo-controlled international study. Patients aged 75 years or younger were eligible for entry if they presented to a coronary care unit within 24 hours of the onset of symptoms of an AMI. Exclusion criteria included current treatment with a β blocker or calcium-channel blocker, heart rate ≤65 beats/min, systolic blood pressure ≤105 mm Hg, contraindications and other administrative reasons. Treatment began with an intravenous loading dose (3 × 5 mg injections of metoprolol or placebo at 2-minute intervals) followed by an oral regime of 200-mg metoprolol daily or placebo. The study period was 15 days in addition to the day of randomization. The patients' clinical history and status at entry were documented. The following outcome variables were recorded: mortality, development of AMI, serum enzyme activity, electrocardiographic signs of AMI, late or recurrent AMI, arrhythmias, treatment of chest pain, concomitant treatment, adverse events and details of treatment with trial medication.

(Am J Cardiol 1985;56:3G–9G)

The trial was double-blind and placebo-controlled. The day of randomization was day 0 and the trial period was defined as days 0 through to and including day 15. Each study day was a 24-hour calendar day, except day 0, which was always less than 24 hours. The important elements of the design of the trial were contained in the final project protocol (dated November 16, 1982), which is available from the authors upon request.

Patients

Selection: All men and women 75 years old or less with either chest pain of acute onset and a suspicion of acute myocardial infarction (AMI) of at least 15 minutes duration, or electrocardiographic signs and symptoms indicating an AMI had occurred within the last 24 hours were eligible for inclusion in the study.

Screening: All patients admitted to coronary care units who were eligible for inclusion were registered in consecutive order in a specific "MIAMI Log Book." The patients were then evaluated with regard to specific exclusion criteria (Table I). The exclusion criteria were evaluated in a hierarchic order according to Table I and the criterion carrying the lowest number was listed for each excluded patient. The reasons for exclusion could be divided into 3 major groups; first, treatment with either β blockers or calcium-channel blockers, second, conventional β-blocker contraindications and third, exclusions for technical and methodological reasons. The MIAMI Log Book was a source of information on all eligible patients. In it, the following information was recorded for all patients: date of arrival, name, year of birth, exclusion criterion or randomization number, date of randomization and whether or not a myocardial infarction was confirmed during the hospital stay. The log book permitted comparison of patients selected for randomization with the excluded patients.

Randomization: All eligible and not excluded patients who had given their informed consent were then randomly allocated to treatment with placebo or metoprolol.

Conduct of the Trial

The clinical management of all symptoms and complications was to be conducted according to local practice. However, certain general recommendations were given in a manual of procedures, which is available from the authors upon request.

Randomization procedure: As soon as possible after the patient had been admitted to the coronary care unit, baseline electrocardiogram (ECG), heart rate and systolic blood pressure were monitored over at least a 10-minute interval. Physical examination including pulmonary auscultation was also performed.

If no exclusion criteria as listed in Table I were met, the patient was then considered suitable for random-

Address for reprints: Åke Hjalmarson, MD, Department of Medicine I, Sahlgren's Hospital, S-413 45, Göteborg, Sweden.

TABLE I Exclusion Criteria

Current treatment with β blockers (any treatment within the previous 48 hours)
Current treatment with calcium-channel blockers (any treatment within the previous 48 hours)
Heart rate ≤65 beats/min during the 10-minute interval
Systolic blood pressure ≤105 mm Hg during the 10-minute interval
Left ventricular heart failure with basal pulmonary rales >10 cm
Signs of poor peripheral circulation, such as coldness and paleness, due to pump failure
AV conduction with P-Q time >0,24 second or higher degree AV block
Severe chronic obstructive pulmonary disease (e.g., requiring long-term treatment with corticosteroids or β_2 stimulants)
Implanted pacemaker
Resuscitation outside hospital (within 24 hours)
Other serious diseases influencing short-term prognosis and general condition (e.g., neoplasm, severe organ insufficiency, cerebral lesions)
Previous participation in MIAMI trial
Participation in other randomized trials
Unwillingness to participate in trial or unable to give informed consent

AV = atrioventricular.

TABLE II Reasons for Temporary and Permanent Withdrawal

Temporary withdrawal
SBP ≤89 mm Hg (caution should be taken with regard to patients with previous hypertension)
Heart rate ≤44 beats/min *and* concomitant signs suggestive of depressed heart function (e.g., SBP ≤89 mm Hg, signs of poor peripheral circulation and pulmonary congestion)
P-Q time >0.26 second
Asystole not related to administration of narcotic analgesics or following defibrillation
Persistent basal lung rales >10 cm despite optimal treatment
Permanent withdrawal
Use of sympathomimetic drugs for the above listed conditions
Asystole, bradycardia or AV block requiring permanent pacemaker insertion
Frequent or severe anginal attacks (e.g., 5 to 10/day) in spite of vigorous treatment with antianginal drugs except β blockers
Supraventricular tachyarrhythmias requiring open treatment with β blockade
Significant bronchial obstruction despite additional treatment with β_2 stimulants

AV = atrioventricular; SBP = systolic blood pressure.

ization. The trial medication was immediately made ready and the cardiovascular status of the patient checked again. If there was still no reason for exclusion, the ampoule containing the intravenous trial medication was opened, and at this point the patient was defined as being randomized into the study.

Trial medication: The intravenous administration of trial medication was given as soon as possible after randomization as 3 rapid injections of 5 ml each (5 mg metoprolol or matching placebo), with 2-minute intervals. Heart rate, systolic blood pressure and ECG were monitored during intravenous administration and 15 minutes thereafter. Before the second and third injections were given, the heart rate should have been >49 beats/min, the systolic blood pressure >99 mm Hg and the P-Q time <0.26 second. Further, it was required that there was no worsening of dyspnea or cold sweating before the second or third intravenous dose was given. If the patients fulfilled these criteria and had no aggravation of dyspnea or cold sweating 15 minutes after completion of the full intravenous injection (15 ml), one-half of the trial tablet (metoprolol 100-mg tablet or matching placebo) was then given.

The standard dose was one-half tablet every 6 hours over days 0 to 2 and thereafter 1 tablet every 12 hours for the remainder of the trial period. Instructions regarding administration and adjustment of trial medication were given in the manual of procedures.

Patients who received a reduced dose of oral medication or no dose during the first 2 days were reassessed for institution of treatment on day 3. Inclusion day is registered as day 0. After day 2, 100-mg metoprolol or placebo was given twice a day until at least day 16. Thereafter, it was recommended that all patients were to be treated openly with metoprolol.

Withdrawal of trial medication: Predetermined guidelines for withdrawal of trial medication and instructions for treatment of different complications and symptoms were specified in the manual of procedures. The criteria for temporary and permanent withdrawal are listed in Table II. If treatment was temporarily withdrawn, the patient was reassessed 2 days later for gradual reinstitution of trial medication. The patient was permanently withdrawn if the medication was withdrawn a second time.

The main principle was to maintain the patients on trial medication, or in case of withdrawal, to reinstitute the medication if possible. The goal was to have the patients on the highest tolerable dose of trial medication throughout the trial period.

Concomitant therapy: The drugs generally used in the treatment of patients with AMI were allowed as described in the manual of procedures. However, the use of other drugs that may have interfered with the evaluation of treatment effects was avoided, especially where a potentially hazardous drug interaction existed. On the other hand, there was an attempt not to be too restrictive in the use of concomitant therapy because an unnecessary high withdrawal of trial medication might have resulted. All β-blocking agents, verapamil and diltiazem were not to be given to patients on trial medication with the exception of verapamil in patients with supraventricular tachyarrhythmias and without left ventricular failure.

Study Variables

All randomized patients were documented according to a standardized Basic Case Report Form (BCRF). Patient information on general clinical history, long-term cardiovascular drug treatment, signs of myocardial infarction on the ECG, treatment in hospital before randomization and clinical status immediately before the blind injection (pulmonary rales, atrial fibrillation, heart rate and systolic blood pressure) was recorded on the BCRF. All effect variables were documented in the BCRF.

Heart rate and systolic blood pressure immediately before blind injection and 15 minutes after completed intravenous administration were documented. A standard ECG was obtained immediately after arrival in hospital. The ECG was continuously monitored over a 10-minute period before and during the injection procedure, and thereafter according to the local routine. The ECG signs were recorded on the BCRF.

The following definitions were used:

Q wave = ≥0.04 second wide and >1 mm deep, or ≥0.03 second wide and Q/R >1/3 and >1 mm deep.

ST-segment elevation = ≥1 mm in leads I, II, III, aVL, aVF, V_5 and V_6, or ≥2 mm in leads V_1, V_2, V_3 and V_4.

Loss of R wave = complete loss of R wave with a reduction in R-wave amplitude of at least 3 mm in 2 electrodes or more, which remained in at least 2 consecutive recordings.

Serum enzyme tests according to the local practice were required once a day during days 0 to 3, and the maximal value was recorded.

Definite acute myocardial infarction (days 0 to 3): Definite AMI was diagnosed if 2 or 3 of the following criteria were fulfilled: (1) chest pain with a duration of at least 15 minutes; (2) two values above the normal range for the enzyme used for infarct definition; and (3) appearance of new Q waves or loss of R waves or ST-segment elevation followed by T-wave inversion in at least 2 electrodes in a 12-lead standard ECG.

Possible acute myocardial infarction (days 0 to 3): Possible AMI was diagnosed if chest pain of at least 15 minutes' duration occurred and any one of the following criteria was fulfilled: (1) appearance of T-wave inversion in at least 2 electrodes in a 12-lead standard ECG without enzyme values above the normal range; (2) only 1 raised enzyme value above the normal range; and (3) appearance of new Q waves or loss of R waves or ST-segment elevation followed by T-wave inversion in only 1 electrode in a 12-lead standard ECG.

Localization of definite myocardial infarction: Definite myocardial infarction was classified as anterior, lateral, inferior, posterior wall infarction or other (to be specified) according to the following definitions:

Anterior wall infarction = criteria for definite myocardial infarction fulfilled in any of the leads V_1 through V_4 in a 12-lead standard ECG.

Lateral wall infarction = criteria for definite myocardial infarction fulfilled in any of the leads V_5 through V_7, I or aVL in a 12-lead standard ECG.

Inferior wall infarction = criteria for definite myocardial infarction fulfilled in any of leads II, III or aVF.

Posterior wall infarction = increase in R-wave in leads V_1 or V_2.

For purpose of presentation, the recorded localizations have been grouped in the following fashion. All anterior includes anterior together with other locations except inferior. All inferior includes inferior together with other locations except anterior. Other locations include other locations, lateral, posterior and anterior together with inferior. Pure anterior and pure inferior have also been presented.

The occurrence of late first or recurrent infarctions during the study periods days 4 to 5 and 6 to 15 was also recorded with application of the same definition for definite myocardial infarction as previously given.

Ventricular fibrillation (VF): The time of each episode of VF was recorded during days 0 to 15. When multiple episodes of VF occurred, a free interval of 2 minutes or more was required before a new episode was registered for analysis. End-stage VF occurring within 24 hours of death was defined as agonal and not included in the analysis if refractory left ventricular failure or cardiogenic shock was present. Clinical observations were recorded based on 2 time intervals: 0 to 5 days and 6 to 15 days.

Occurrence of auscultatory basal pulmonary rales (more than sparse rales) indicating congestive heart failure and requiring treatment was noted. The use of any diuretics was documented. Additionally, the total dose of furosemide if used or the calculated equipotent doses of other diuretics as well as the number of injections were recorded. The time of last narcotic analgesic injection was recorded as well as the number of injections.

Hypotension, bradycardia, atrioventricular block, pacemaker insertion, supraventricular tachyarrhythmia, ventricular tachycardia, asystole, cardiogenic shock and different cardiac medications were noted.

Temporary and permanent withdrawal of trial medication was noted as were the reason and the time of permanent withdrawal. Adverse events possibly related to the trial medication were recorded. The exceptions were hypotension, bradycardia, heart failure and atrioventricular block.

The patient's compliance with treatment was judged by tablet counts. The days on which patients received full dose, half dose, quarter dose and no dose were also registered.

Information on time, place, cause and mode of death was recorded. The occurrence of cardiac rupture was documented in all patients in whom autopsy reports were available.

The primary endpoint in the trial was death from all causes during the trial period, days 0 to 15.

The secondary endpoints were: (1) the sum of both deaths and patients with nonfatal VF during days 0 to 5; (2) definite myocardial infarction during days 0 to 3; (3) infarct size estimated from serum enzymes during the first 3 days; (4) definite myocardial infarction from days 0 to 5 and days 0 to 15; (5) late first infarction during days 4 to 15; (6) recurrent infarction during days 4 to 15; (7) cardiac death and mode of death during days 0 to 5 and days 0 to 15; (8) noncardiac death during days 0 to 5 and days 0 to 15; (9) incidence of VF (both nonfatal and fatal, number of patients and episodes) and presence of left ventricular heart failure/congestive heart failure (number of patients and use of diuretics) and chest pain (pain duration and use of analgesics) during days 0 to 5 and days 0 to 15; and (10) tolerance, safety and adverse events during days 0 to 15.

TABLE III The Responsibilities of the Steering Committee

Preparation of the study protocol, case report forms and manual of procedures
Recruitment of investigators and provision of guidance to the trial centers
Making all ethical, scientific and policy decisions
The practical running of the study
Acting upon recommendations of the Safety Monitoring Committee
Collecting, editing and storing all data received from the trial centers
Monitoring and maintaining quantity and quality of data flow
Preparing the periodic progress reports for the Advisory Committee and trial centers
Preparing reports from the trial for publication
Blind classification of all endpoints

Organization

A formal organizational plan was established (Fig. 1). Steering, Advisory, Safety Monitoring and Independent Data Audit Committees were formed. The Steering Committee also established 4 different subcommittees: Economy and Administration, Statistical, Data Coordinating and Data Management.

The Steering Committee consisted mainly of investigators from the Göteborg Metoprolol Trial.[1] The Steering Committee was primarily responsible for preparation of the project protocol, BCRFs and manual of procedures. This committee was also responsible for recruitment of investigators. The responsibilities of the Steering Committee are listed in Table III. A Publications Subcommittee was formed from within the Steering Committee.

The Advisory Committee was selected by the Steering Committee and consisted of experienced cardiologists from different participating countries. The Advisory Committee was responsible for approving the scientific and ethical design of the study and advised the Steering Committee on major policy decisions. The Advisory Committee also reviewed the scientific reports before publication.

The Safety Monitoring Committee was selected by the Steering Committee and was composed of 3 physicians with training in epidemiology and clinical trial methodology and 1 statistician.

An important function specified in the protocol was that the Safety Monitoring Committee would carefully monitor the results at regular intervals to detect as soon as possible any harm from the treatment, which would cause premature closure of the trial. The protocol also stated that because such periodic monitoring was associated with an increased risk of a false-positive finding, the method of O'Brien and Fleming[2] in deciding a statistically significant result was to be used. The Safety Monitoring Committee analyzed selected endpoints after approximately 1,500, 2,000, 3,000 and 4,000 patients were randomized, and found no cause to recommend a premature termination of the study. The results of these analyses were kept within the Safety Monitoring Committee except for the data of the 4,000 patients, which were discussed confidentially with the Advisory Committee.

Other responsibilities included reviewing and endorsing general methodology and statistical analyses, and presenting periodic reports to the Steering Committee.

The Independent Data Audit Committee, selected by the Steering Committee, consisted of a statistician located in Oslo, Norway. He was responsible for checking and notification of randomized patients and deaths. These data were obtained directly from each trial center. This committee guaranteed that no technical errors or erroneous statistical analyses were made in relation to objectives stated in the project protocol. Site visits were made to the Data Management Center during the trial to ensure correspondence between these 2 data bases and to audit procedures.

One hundred and four centers from 17 countries participated in the MIAMI trial. The Data Coordinating and Data Management Subcommittees were merged early after starting the study to form a Data Management Center in Göteborg, which was composed of scientific and administrative staff of AB Hässle and a data auditor appointed by the Steering Committee. Local data centers were established in each

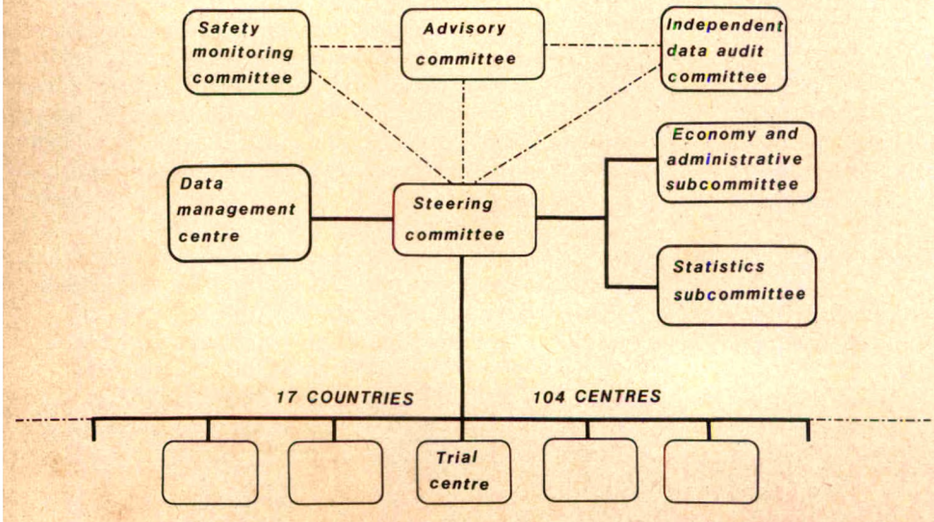

FIGURE 1. Plan of MIAMI trial organization.

participating country and were staffed by clinical trial monitors from the local Astra companies. This project organization was responsible for constructing and continuously updating a computerized data base of all study variables.

The protocol was reviewed and approved by the responsible ethical review committee at each of the participating trial centers. At all trial centers the patients were fully informed regarding the trial and consented to participate, at least verbally.

Statistical Methods and Analyses

In estimating sample size, a 7% mortality rate was assumed for the placebo group. To detect a 35% reduction in mortality in the metoprolol group with 90% probability using a 2-sided test at the 5% significance level, it was calculated that 4,000 patients with a suspected myocardial infarction at entry were needed. This would yield approximately 2,400 patients (60%) with a confirmed diagnosis of AMI. Because patients could be entered before their presumed myocardial infarction status was confirmed, a substantial portion of patients without a definite myocardial infarction were expected to be randomized.

Because this trial was to be conducted in several countries, there was uncertainty regarding the applicability of the just mentioned assumptions about mortality and the percentage of definite myocardial infarctions derived from previous smaller studies mostly performed in Scandinavia. The consequent impact may have been a smaller number of events than anticipated, and so to compensate for this loss of statistical power, an increase of sample size was allowed for. If the average mortality rate for the 2 treatment groups was <5% when 2,000 patients had been randomized, the sample size was permitted to be increased to 5,200 patients. This would have corresponded approximately to 3,200 patients with definite myocardial infarctions. This increase would have given a 90% probability of establishing a 35% difference as significant if the mortality was only 5% in the placebo group.

The statistical test of the 15 day mortality was done with Fisher's exact test in 4-fold tables. Mantel-Haenszel's method was used to test differences in survival curves. A 2-tailed test with a p value ≤ 0.05 was regarded as significant. The nominal p values rounded to 2 most significant digits have been presented when <0.10 throughout.

Subgroups were formed based on certain baseline and diagnostic variables. Quantitative variables were dichotomized at the quartiles or the median. Differences were tested with Fisher's exact test, 2-tailed. The p-value conventions just described were applied.

Some subgroups were proposed in the protocol (subgroup hypotheses) and others formed retrospectively. These differentiations are stated in reporting the results.

Multivariate analyses: For such binary response variables as death, definite myocardial infarction and use of narcotic analgesics, the effect of drug and important baseline variables and possible interactions between drug and baseline variables have been analyzed with logit models.[3] Logit analysis of categorical data can be looked upon as a counterpart of regression analysis of continuous response variables.

The analysis began with a basic set of predictors, proceeded with the fit of an adequate model based on previous knowledge and expectations and included main effects of the predictors and reasonable interactions between drug and other predictors. Tests similar to those performed in regression analysis were done to test the significance of individual predictors.

This multivariate model approach, which simultaneously considers the effect of all variables in the basic set, is much more appropriate than a subgroup analysis in which only 1 predictor at a time is taken into consideration. The multivariate analysis avoids the confounding of effects of different variables as far as all relevant variables are included in the basic set. The multiplicity test problem is present but not to the same extent as with a detailed subgroup analysis.

The requirement for an adequate model fit was set to $p > 0.15$ and the significance level for the test of the effect of individual predictors was set to 5%.

Randomization code: All patients included in the trial were given a consecutive patient randomization number that was printed on the trial medication ampoules and bottle. The randomization code was stratified only by trial center. The randomization code was computer-generated on a microcomputer by a member of the Safety Monitoring Committee, independently of all other organizing committees and the sponsor of the trial. Only 4 sets of the randomization code were generated, 1 for the Chairman and 1 for the statistician of the Safety Monitoring Committee, 1 for the Pharmacy Department at the Östra University Hospital whose members were responsible for packing the clinical trial material and 1 for emergency use. This last code was provided sealed in separate envelopes for individual patients at each trial center. The code list was produced in blocks of 50 and towards the end of the study in blocks of 16.

Each block contained equal numbers of patients on the 2 treatments randomly ordered in such a way that the difference in numbers on placebo and metoprolol never exceeded 3 when starting from the beginning of the block. This enabled a good balance to be achieved within each center. The block constituted different random permutations of the treatments with the 2 restrictions mentioned above.

Packaging and Distribution of Trial Medication

For each randomized patient there were 4 ampoules of 5 ml (metoprolol tartrate 1 mg/ml or normal saline placebo) and a bottle containing 40 tablets (metoprolol tartrate 100 mg or placebo). These formulations were supplied by AB Hässle, a subsidiary of AB Astra, Sweden.

Packaging and labelling according to the randomization code were done in the Department of Pharmacy of the Östra University Hospital in Göteborg. The stock was packaged in sets of 50, together with the individual code sealed in 50 separate envelopes and with the BCRFs, and then distributed to the trial

centers. The procedure was performed in this way so that the study could be conducted blindly by the organizing committees, the investigators, the patients and the sponsor.

Data Management and Monitoring Procedures

The data collected by each trial center were recorded on 4 different case report forms. A patient recruitment information slip containing randomization number and date was completed when a patient was randomized and copies were distributed according to Figure 2. Within a few weeks, the Data Management Center and the Independent Data Audit Committee were informed of each patient who had entered.

Copies of the log book and BCRF were distributed according to Figure 3. The BCRF was a 9-page booklet; the first 8 pages were in 3 copies (white, blue and yellow) and the ninth page had 4 copies (white, blue, yellow and pink). Completed log books and BCRFs were collected personally by a study monitor approximately every month and thus within 2 months of randomization, these data were usually at the Data Management Center. The Independent Data Audit Committee received the mortality data on the pink copy of page 9 of the BCRF within a similar time.

Quality control and data base procedures: BCRFs completed at the trial center and signed by designated investigators were subject to quality checks at these stages:

Stage 1 at the trial center, by the Astra monitor. Uncertainties were clarified before copies were removed.

Stage 2 at the Data Management Center in Sweden, by a data auditor appointed by the Steering Committee. Uncertainties were noted on a data clarification form, which was returned to the trial center for clarification.

Stage 3 at the Data Management Center, using a computerized input and editing system (CHIVAS [Computerized Hässle Input, Validation and Access System]). This system used a screen form of each page of the BCRFs as an entry mode and provided error reports on missing data, out-of-range data and internal inconsistencies within a patient's data. Errors detected were noted on a data clarification form and returned to the trial center for clarification.

Stage 4 at the Data Management Center, using editing programs on the data base. After data had been entered to the data base via CHIVAS, extensive checks were conducted using programs to identify any logical inconsistencies that the CHIVAS system could not detect during the input phase. Uncertainties were clarified by the trial center using a data clarification form as described previously.

Data base integrity: During the validation and input phase, conventional data processing routines for confidential data were applied, i.e., only authorized staff had access to the data. Access to the computer programs was further restricted by means of a series of passwords changed frequently.

A data control document was used to record the transfer of responsibilities, the dates for completion of the scheduled actions and the detected error rates. The data control document was stored together with the case report form to serve as an independent check that the data base remained intact.

Data file transfer: After patient recruitment ended on March 31, 1984, and the 15 days' follow-up was completed, all log book and BCRF data were entered and validated in the data base using the just described procedures by early May 1984. At this time the Independent Data Audit Committee corroborated the number of randomized patients and mortality data in the data base at the Data Management Center and approved the start of the data analysis. The data file was then transferred from the Data Management Center to the University of Göteborg where, for the first time, the code was entered and analyses begun.

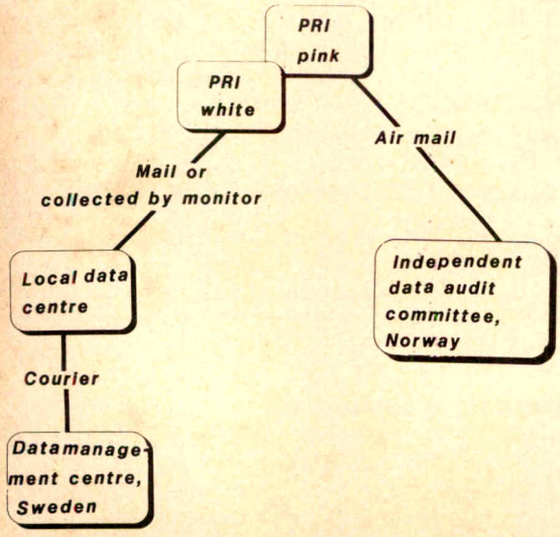

FIGURE 2. Flow chart for the patient recruitment information (PRI) forms.

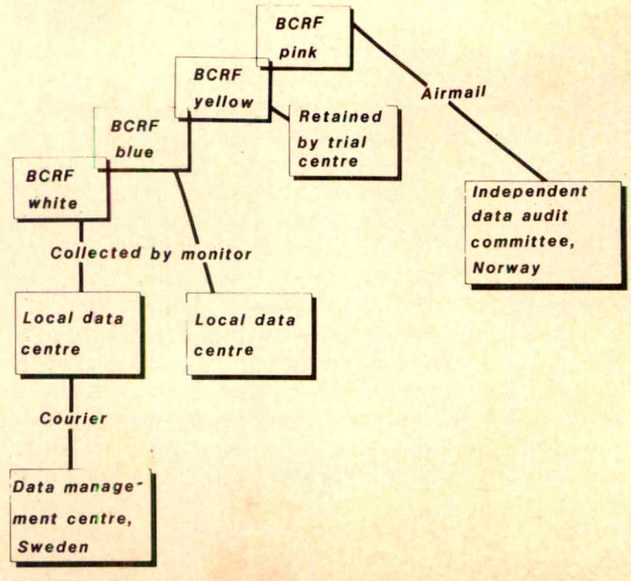

FIGURE 3. Flow chart for the basic case report forms (BCRFs).

In summary, a trial needs to include enough patients to yield a sufficient number of endpoints to allow statistical analysis at a satisfactory level of significance and with a reasonable likelihood of reaching that result. Only an analysis including all randomized patients regardless of subsequent fate is devoid of bias from the investigators and analysts.

It has been argued that the chronotropic effect of β blockers precludes the maintenance of blindness in placebo-controlled studies. It has also been proposed that the use of indisputable endpoints, such as death from any cause, would reduce bias such that a blinded design was unnecessary. In all studies of β blockers, the average heart rate in the β-blocker group of patients has to be lower than in the placebo group. However, the variance in both treatment groups has always been sufficiently great to cause a large overlap between the 2 groups. For this reason, there is uncertainty in the prediction of the actual treatment in any individual.

Maintenance of the highest possible degree of blindness was seen to be particularly important when it was shown that even nonspecific measures, such as good medical practice, may have a substantial impact on reinfarction and deaths without the use of any pharmacologic intervention.[4,5]

Patient Population

The MIAMI Trial Research Group

During the recruitment phase of the MIAMI trial (December 1982 to March 1984), data on 26,439 patients eligible for inclusion were entered. Of these, 5,778 patients were included. Current treatment with either β blockers or calcium-channel blockers (51%) was the most predominant reason for exclusion. The randomized and excluded patients differed. The randomized patients were younger and more often men. The mean age of the patients was 59 years in both the placebo and the metoprolol groups. The 2 groups were evenly balanced with regard to basic demographic variables. The median delay between onset of symptoms and randomization was 7 hours, and 25% of the patients were included within 4 hours. Previous clinical history and pharmacologic treatment given before admission were well balanced in the groups. Mean heart rate for the 2 groups before randomization was 83 beats/min and systolic blood pressure was 141 mm Hg. Approximately 15% of randomized patients presented with pulmonary rales. Before randomization 20% of the patients had normal electrocardiograms; 70% could be classified as having electrocardiographic signs of acute myocardial infarction; and 10% presented with other electrocardiographic abnormalities. Electrocardiographic signs at entry suggested a predominance of anterior wall infarctions. The randomized patients were not representative of eligible patients and the treatment groups were well balanced at entry.

(Am J Cardiol 1985;56:10G–14G)

This article will present the outcome of the patient selection procedure and compare the patient sample randomized into the MIAMI trial with the patients excluded. It also examines the comparability of the 2 treatment groups with respect to baseline characteristics. The methodology concerning patient screening and randomization was presented in full in the preceding article.

Results

During the recruitment phase of the trial, which took place between December 1982 and March 1984, data on 26,439 patients eligible for inclusion were entered into the MIAMI Log Books (Table I, Figs. 1 and 2). Of these, 20,661 were excluded. The remaining 5,778 patients did not meet any of the 14 exclusion criteria and were subsequently randomized into the study.

Current treatment with either β blockers or calcium-channel blockers was the most predominant reason for exclusion (51.1%). Other reasons for exclusion are listed in Table I.

Table II lists the reason for the exclusion of patients in various age categories. There was a positive correlation between increasing age and exclusion rate because of left ventricular failure, atrioventricular-conduction disturbances and chronic obstructive pulmonary diseases, while the reverse was true for those excluded

TABLE I Eligible Patients with MIAMI Log Book Inclusion and Exclusion Criteria (for patients with multiple exclusion criteria the first is listed)

Eligible patients		26,439 (100)
Excluded patients		
Current β-blocker treatment	8,205 (39.7)*	
Current calcium-channel blocker treatment	2,358 (11.4)	
Heart rate ≤65 beats/min	4,190 (20.3)	
Systolic blood pressure ≤105 mm Hg	1,081 (5.2)	
Left ventricular failure, rales >10 cm	1,422 (6.9)	
Poor peripheral circulation	164 (0.8)	
AV-conduction disturbance	439 (2.1)	
Chronic obstructive pulmonary disease	638 (3.1)	
Implanted pacemaker	115 (0.6)	
Out-of-hospital resuscitation	233 (1.1)	
Other serious disease	369 (1.8)	
Previous MIAMI trial participation	207 (1.0)	
Participation in other studies	167 (0.8)	
Unwillingness	1,063 (5.1)	
(Information missing)	(10)	
Total		20,661 (78.1)
Randomized patients		5,778 (21.9)

* Numbers in parentheses indicate percentages of all eligible or excluded patients.
AV = atrioventricular.

TABLE II Percentage of MIAMI Log Book Exclusion Criteria in Different Age Groups

	Age (years)				
	<39	40–49	50–59	60–69	>70
Exclusion criteria					
Current β-blocker treatment	38.6	38.5	41.9	41.1	35.4
Current calcium-channel blocker treatment	9.1	8.6	10.8	11.9	12.7
Heart rate ≤65 beats/min	21.8	25.7	22.1	19.0	18.0
Systolic blood pressure ≤105 mm Hg	5.6	6.3	5.1	4.9	5.6
Left ventricular failure	1.6	3.4	4.7	7.2	10.8
Poor peripheral circulation	0.5	0.8	0.7	0.8	0.9
AV-conduction disturbance	1.4	1.8	1.7	1.9	3.1
Chronic obstructive pulmonary disease	1.9	1.8	2.3	3.7	3.5
Implanted pacemaker	0.2	0.2	0.4	0.6	1.0
Out-of-hospital resuscitation	1.4	0.9	1.2	1.1	1.1
Other serious diseases	2.3	0.8	1.5	1.8	2.5
Previous MIAMI inclusion	1.4	1.6	0.9	0.9	0.9
Participation in other studies	1.9	1.5	1.2	0.7	0.1
Unwillingness	12.2	8.1	5.5	4.4	4.3

AV = atrioventricular.

because of participation in other trials and unwillingness to participate in the MIAMI trial.

The randomized and excluded patients differed with regard to age and sex (Table III); the randomized patients were younger and more often men. Of those patients younger than 50, approximately 30% were randomized; less than 20% of those older than 70 were randomized. The proportion of patients with confirmed definite myocardial infarction according to the study criteria was higher among the randomized patients (74.1% vs 60.6%).

All but 74 patients fulfilled the entry age criteria of age <75. Only 4 of these were >75 years. Seventy-seven patients had heart rates ≤65 beats/min and 29 patients had systolic blood pressures ≤105 mm Hg.

Randomized patients: Data from the placebo and metoprolol groups with regard to age, sex, race and delay from onset of symptoms to injection are presented in Table IV. The mean age of the patients in the 2 groups was approximately 59 years, the majority of patients were white men and the 2 groups were evenly balanced with regard to basic demographic variables. In the 2 treatment groups the median delay in time between onset of symptoms and randomization was

Age (years)			
<39	4.0	2.1	35
40–49	15.0	9.2	31
50–59	28.7	25.8	24
60–69	35.5	41.0	20
>70	16.8	21.8	18
Age (years)			
Mean ± SD	58.9 ± 10.1	61.4 ± 9.2	
Median	60.0	63.0	
Q_1	52.0	56.0	
Q_3	67.0	69.0	

MI = myocardial infarction; Q_1 = lowest quartile; Q_3 = highest quartile; SD = standard deviation.

approximately 6.7 hours; 25% of the patients were included within 4 hours and 75% of the patients within 12 hours. The median delay in time between onset of symptoms and admission to hospital was 3.3 hours. Previous clinical history and long-term pharmacologic treatment given before admission are presented in Table V.

Adminstration of drugs given after arrival in hospital but before randomization is presented in Table VI. The rates did not differ with respect to cardiac glycosides, diuretics and atropine.

Baseline heart rate, systolic blood pressure and frequencies of pulmonary rales, atrial fibrillation or flutter and ventricular fibrillation before randomization into the study are listed in Table VII. Mean heart rate for the 2 groups before randomization was 83 beats/min and mean systolic blood pressure was 141 mm Hg. Approximately 15% of patients presented with pulmonary rales; ventricular fibrillation before entry occurred in 2%.

Electrocardiograms classified before randomization are listed in Table VIII. Before randomization 20% of the patients had normal electrocardiograms; 70% could be classified as having signs of acute myocardial infarction; and 10% presented with other abnormalities. The predominant site of the acute myocardial infarction on presentation was the anterior wall.

The amount of trial medication injected in the 2 treatment groups is listed in Table IX. Between the evaluation of the patient and the actual injection, the ampoule was broken in 24 patients in the placebo and 15 patients in the metoprolol group but the patients deteriorated and the injections were not given. Almost all patients were injected with the full dose. A higher proportion of metoprolol patients did not tolerate the full 15 ml ($p < 0.001$). Most patients were also given the full initial oral dose 15 minutes after end of injection (Table X). More patients in the metoprolol group received reduced or no initial oral dosage ($p < 0.001$).

After full intravenous dose, no or reduced oral doses were given to more patients in the metoprolol group ($p < 0.001$, Table XI).

Discussion

According to calculations based on the Göteborg Metoprolol Trial,[1] an inclusion rate of approximately 25% of eligible patients was expected. The observed rate was slightly lower. The relative frequencies of the exclusion criteria are difficult to compare with other studies and patient groups because they were coded according to a consecutive order. Thus the selection of the first criterion influences all rates of subsequent criteria.

The selection criteria in this study were not conventional. The aim was not to recruit all patients without contraindications to β blockade, but instead to focus

on a subset of patients with a higher sympathetic activity, who were hypothesized to be at higher risk and more likely to benefit from metoprolol treatment. Consequently, of the excluded patients, 50% were excluded because they were receiving treatment with β blockers or calcium-channel blockers; another 25% did not have a high enough heart rate or systolic blood pressure; and another 13% had standard β-blocker contraindications.

It was not surprising, therefore, to find differences between the randomized and excluded patients with respect to age and sex distributions. It was somewhat remarkable, however, to observe a higher rate of confirmed infarctions among the randomized patients compared with excluded patients. It was also apparent that more contraindications to β blockade were found in higher age groups.

TABLE XI Initial Treatment. Reduced Trial Drug Administration

	Placebo (n = 2,901)		Metoprolol (n = 2,877)	
	%	n	%	n
Full intravenous–no oral dose	0.4	12	1.8	53
Full intravenous–reduced oral dose	0.5	15	2.5	71

The randomization procedure was effective in that the placebo and metoprolol groups appear well balanced regarding individual baseline variables of prognostic importance.

It can be concluded that, in accord with the study objectives, the randomized patients were not representative of all eligible patients and the treatment groups were well balanced at entry.

Lancet 1981;2:823–827.

Mortality

The MIAMI Trial Research Group

After 15 days there were 142 deaths in the placebo group (4.9%) and 123 deaths in the metoprolol group (4.3%), a difference of 13% (p = 0.29). The 95% confidence limits for the relative effect of metoprolol ranged from an 8% excess (−8%) to a 33% reduction (+33%) in mortality. There was generally a lower mortality rate for metoprolol-treated patients in most subgroups and a consistent tendency for a more pronounced difference between the treatment groups in those subgroups with a placebo mortality rate higher than the average for all placebo patients. Most deaths were cardiac and occurred among patients who developed a definite myocardial infarction (97%) and most of these had a Q-wave infarction (83%). Using a simple model, the placebo mortality was found to increase with increasing number of 8 risk predictors defined from prestudy experience, from 0% in patients with no risk predictors to 11.6% in patients with any 5 or more of these risk factors. Similarly, there was an increase in the difference between the treatment groups in favor of metoprolol with increasing number of placebo risk factors. Metoprolol had no apparent effect in a low-mortality risk group (≤2 risk factors), but there was a difference in mortality of 29% in favor of metoprolol in a high-risk group (≥3 risk factors) comprising one-third of the trial population. A multivariate model provided further evidence that the effect of metoprolol was not uniform among different risk categories based on clinical history and status at entry. There was no tendency for a significant drug effect in the low- and medium-risk classes. In the high-risk class constituting 23% of patients, however, there was an indication of a beneficial effect estimated as 39% reduction of mortality (95% confidence interval: +4 to +61%).

(Am J Cardiol 1985;56:15G–22G)

During the last 2 decades a large number of randomized placebo-controlled trials have been performed using β blockers in the treatment of survivors of an acute myocardial infarction (AMI).[1] A beneficial effect on mortality by β blockade has been demonstrated mostly in late-entry studies with start of treatment 1 to several weeks after onset of infarction.[2,3] The total mortality reduction has averaged around 25%. It is now widely accepted that β blockade can improve long-term survival after AMI.

A smaller number of studies involved early start of treatment in AMI patients shortly after their arrival in a hospital.[4] The Göteborg Metoprolol Trial[5,6] showed a significantly lower total mortality in the treated group at the end of 3 months of follow-up.

The primary objective of the present trial was to evaluate further the effects of metoprolol on total mortality during the first 15 days after onset of suspected AMI. According to the protocol, subgroups were formed with respect to delay time, heart rate and suspected site of infarction at entry.

Patients and Methods

All randomized patients were included. Information on the time, place (in or outside hospital), cause (cardiac or noncardiac) and mode of death was recorded.

Cardiac deaths were classified as end-stage left ventricular failure/congestive heart failure with or without lethal arrhythmias; primary lethal arrhythmias including ventricular fibrillation and asystole; sudden circulatory collapse; other; and unknown. Sudden circulatory collapse includes suspected or proven rupture of ventricular wall without observed arrhythmias or block. Among autopsied patients rupture of ventricular wall was recorded.

For descriptive purposes, mortality has also been examined in association with other outcome variables such as final diagnosis of and site of infarction (days 0 to 3). No statistical testing has been conducted on such associations.

Statistical analyses: The standard principles of statistical analyses[7] were applied. The mortality data from day 0 to day 15 have been analyzed on the "intention-to-treat" basis for all 5,778 patients randomized into the study.

Multivariate analyses were conducted to determine if the effect of metoprolol was dependent on baseline risk.[7] The study documented baseline variables known to be risk predictors of short- and long-term mortality rates.[8,9] These risk predictors have been considered in the multivariate analyses

* For a few patients, some data on baseline characteristics were unavailable. Hence data in some subgroups do not equal total patients.

† % difference in mortality = (placebo mortality − metoprolol mortality) × 100/placebo mortality.

‡ Two patients in the placebo group were lost to 15 days' follow-up at the time the code was broken and were assumed to be alive in these calculations. One of these patients has subsequently been confirmed as alive.

aimed at determining how these baseline variables individually contribute to mortality risk in this patient sample and thus develop a mortality risk function from which an aggregate risk of dying within 15 days can be calculated for each patient. In developing this risk function, an assessment of whether specific risk predictors also influence the effect of metoprolol was also attempted. Two-tailed p values are given without any correction for multiple significance testing.

Two approaches were used. The first approach has been reported previously[10] and uses a risk function derived from 8 baseline variables: age >60 years (median), abnormal signs on electrocardiogram (ECG), history of myocardial infarction, hypertension, angina pectoris, congestive heart failure, diabetes, short- or long-term treatment with diuretics or cardiac glycosides. The mortality rate was examined in 6 risk groups in which patients had 0, 1, 2, 3, 4 and ≥5 of any of these risk factors. Two groups were formed retrospectively: a low-mortality risk group (≤2 risk factors) and a high-risk group (≥3 risk factors).

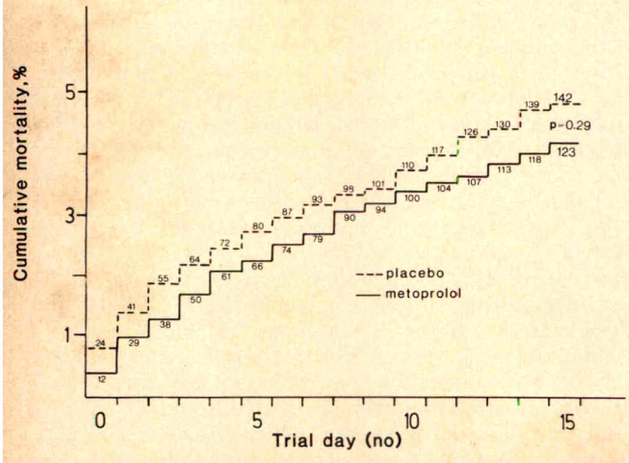

FIGURE 1. Cumulative percentage of mortality and number of deaths by time in the 2 treatment groups.

The second approach uses the logit model,[7,11] which is similar to a logistic regression model and enables the assessment of how the death risk varies with these risk predictors and if the effect of metoprolol varies with 1 or more of these predictors. The following 6 possible predictors of death risk were evaluated in a logit model for mortality within 15 days: age (3 classes, ≤54, 55 to 64 and ≥65 years), signs on ECG at entry (2 classes, normal and abnormal), risk group based on clinical history and status at entry (3 classes, low, medium and high), geographical region (3 classes, countries outside Europe, continental Europe and the United Kingdom, and Finland, Norway and Sweden), delay time (3 classes, <4, 4 to 8 and >8 hours) and drug (2 classes, placebo and metoprolol).

The clinical status variable of risk was defined as follows: high required that at least 1 of the risk indicators was present (history of myocardial infarction, congestive heart failure or diabetes); medium required that no indicator from the high-risk group was present but at least 1 of history of angina pectoris or hypertension, heart rate ≥90 beats/min or short-term treatment with diuretics in-hospital before randomization; and low required that no risk indicator belonging to the high and medium class was present.

The measure of death risk used in the logit model was the odds of death (the probability of death divided by the probability of survival).

§ Baseline variables predicting mortality not well balanced (delay time was not important in a multivariate analysis).
AMI = acute myocardial infarction; ECG = electrocardiogram; HR = heart rate; SBP = systolic blood pressure.

Results

After 15 days there were 142 deaths in the placebo group (4.9%) and 123 deaths in the metoprolol group (4.3%), a difference of 13% ($p = 0.29$). The 95% confidence limits of the relative effect of metoprolol ranged from an 8% excess (−8%) to a 33% reduction (+33%) in mortality. The cumulative mortality was always higher in the placebo group (Fig. 1).

Univariate analyses: Mortality was examined in relation to baseline variables (Tables I, II and III). Concerning the average effect in all patients, there was

TABLE IV Mortality in Subgroups in Relation to Final Infarct Diagnosis and Site Defined During Days 0 to 3

Group	No. of deaths (pts. in group) Placebo	Metoprolol
Myocardial infarction		
None	2 (639)	1 (635)
Possible	2(161)	2 (214)

generally a lower mortality for metoprolol-treated patients in most subgroups. Further, there was a consistent tendency for a more pronounced difference between the treatment groups in those subgroups with a placebo mortality higher than the average for all placebo patients.

From information collected during study days 0 to 3, patients were diagnosed as having definite, possible or no AMI. Patients with definite AMI were classified into those with and without Q-wave infarction and according to site of definite AMI (Table IV). Most deaths occurred among patients who developed a definite AMI (97%) and most of these had a Q-wave infarction (83%).

Table V shows that most deaths occurred in the hospital and were cardiac. About half of the patients

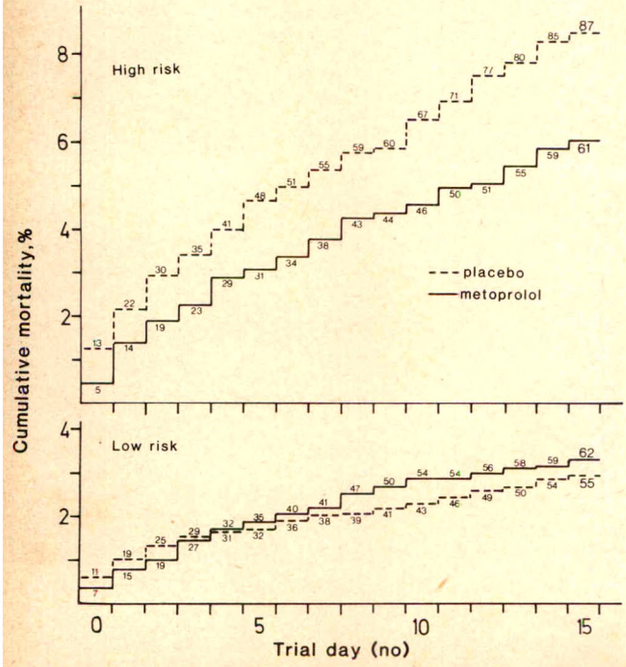

FIGURE 2. Cumulative percentage of mortality and number of deaths by time in the 2 treatment groups and according to risk group assignment (see Table VI).

TABLE V Classification of Deaths

Classification	No. of deaths (% in group of deaths) Placebo	Metoprolol
All deaths	n = 142	n = 123
Place of death		
In hospital	129 (91)	115 (93)
Out of hospital	13 (9)	8 (7)
Cause of death		
Cardiac	138 (97)	118 (96)
Noncardiac	4 (3)	5 (4)
All in-hospital deaths	n = 129	n = 115
Heart failure (LVF/CHF)		
Without arrhythmias	40 (31)	36 (32)
With arrhythmias*	29 (22)	27 (23)
Arrhythmias* or block without LVF/CHF	32 (25)	28 (24)
Sudden circulatory collapse†	21 (16)	19 (17)
Other	6 (5)	5 (4)
Unknown	1 (1)	0 (0)
Autopsy performed	n = 75‡	n = 67‡
Rupture of ventricular wall	39 (52)	32 (48)

* Lethal arrhythmias including ventricular fibrillation and asystole.
† The majority of patients were clinically judged to have a rupture of ventricular wall and most verified by autopsy.
‡ Autopsy was performed in 53 and 54% of all deaths in the placebo and metoprolol groups, respectively, often to verify suspected rupture.
CHF = congestive heart failure; LVF = left ventricular failure.

had heart failure and as many showed arrhythmias or block with or without concomitant heart failure. The proportion of such events in the treatment groups was very similar. Approximately 50% of the patients in both groups had signs of ventricular wall rupture on autopsy.

Analyses with a simple risk predictor: Using the simple model, the placebo mortality was found to increase with increasing number of the 8 risk predictors present (Table VI), from 0% in patients with no risk predictors to 11.6% in patients with any 5 or more of these risk factors. Similarly there was an increase in the difference between the treatment groups in favor of metoprolol with increasing number of risk factors. Baseline characteristics for the placebo- and metoprolol-treated groups were comparable within the low- (≤2 risk predictors) and high- (≥3 risk predictors) risk groups, respectively. Metoprolol had no apparent effect in the low-mortality risk group (95% confidence limits for the relative metoprolol effect −54 and +28%) but there was a difference in mortality of 29% (95% confidence limits +5 and +53%) in favor of metoprolol in the high-risk group (2,038 patients), constituting one-third of the trial population (Table VI, Fig. 2).

Multivariate analysis: In the logit model, the 4 predictors age, ECG, geographical region and risk had significant and independent effects on the odds for death. Delay time did not have a significant association with the risk of death nor was there a significant interaction between delay and the effect of metoprolol. Delay was therefore excluded from the model. Further analyses were based on the contingency table that included status (dead or alive), age, ECG, geographical region, risk and drug. In this model all predictors ex-

cept drug had a significant association with mortality risk ($p \leq 0.005$ for all) and the influence on the placebo patients is illustrated in Figure 3. The overall fit of the model was good ($p = 0.89$). Models including an interaction between drug and one of the other predictors were considered but only the interaction between drug and risk was non-negligible with a p value of 0.17. This interaction was not significant but the power of the interaction test is probably weak in the absence of a strong main drug effect. Because the interaction pattern with a more pronounced effect in the high-risk group (Fig. 4) seemed very reasonable, this interaction was investigated further. This logit model was tested against other similar models in which other interactions between drug and one of the other predictors were added and against models in which 1 predictor was deleted. These other interactions were weak and none of the alternative models gave a better fit to the observed data than the chosen model. There was a tendency for the drug effect to increase with increasing age, but this interaction was less pronounced than that with the risk group and so was not included in the model.

The logit analysis indicates that the uncertainty about the effect of metoprolol on the risk of death is large and that the effect is perhaps not uniform in the different risk classes (Fig. 4). The 95% confidence intervals for the difference in the death risk between placebo- and metoprolol-treated patients are −63 to +40% for the low-risk group, −56 to +29% for the medium-risk group and +4 to +61% for the high-risk group. These are nominal 95% confidence limits without correction for multiple comparisons. The high-risk group consisted of 23% of all randomized patients and 40% of the placebo deaths. The possibility of a strong beneficial effect of metoprolol in the high-risk group was further investigated by examining the *observed* death rates. Figures 5 and 6 show the observed death rates in the different age classes and in the different geographic regions, respectively, among patients with abnormal signs on ECG and belonging to the high-risk class. In the high-risk class, metoprolol mortality was lower than placebo mortality in all 3 age classes and throughout the 3 geographic regions. There is consistency within the data for the high-risk class. When the data were broken down simultaneously according to age and geographic region for patients in the high-risk class, metoprolol-treated patients showed a lower mortality than placebo-treated patients in all 9 cells except 1 in which they were equal (Fig. 7).

TABLE VI Total Mortality in All Patients in Various Mortality Risk Groups Defined from Baseline Risk Predictors*

No. of Risk Predictors Present	% mortality (no. of deaths/pts) in Group: Placebo	Metoprolol	Difference† %
0	0.0 (0/259)	0.0 (0/207)	0
1	1.4 (11/790)	1.8 (15/820)	−32
2	5.3 (44/825)	5.6 (47/839)	− 5
3	6.4 (31/482)	5.6 (27/486)	14
4	9.1 (26/286)	7.0 (21/302)	24
≥5	11.6 (30/259)	5.8 (13/223)	50
≤2 (low risk)	2.9 (55/1,874)	3.3 (62/1,866)	−13
≥3 (high risk)	8.5 (87/1,027)	6.0 (61/1,011)	29

* The 8 risk predictors were: age >60 years (median); abnormal ECG at entry; history of myocardial infarction, angina pectoris, congestive heart failure, hypertension or diabetes; long- or short-term treatment with diuretics or cardiac glycosides before randomization.
† % difference in mortality (see Table I).

Discussion

The MIAMI trial was designed to study the effect of early intervention with metoprolol in a selected group of suspected AMI patients having a predicted placebo mortality rate of 7% after 15 days. The sample size was calculated to detect a difference of 35% in mortality between the 2 treatment groups with a power of 90% (2-sided, $p < 0.05$). The project protocol allowed for an increase in the sample size if the total mortality was lower than assumed after 2,000 patients were entered. The final placebo mortality rate (4.9%), however, was still lower than anticipated. Clearly, a considerable proportion of the randomized patients were low-risk patients who had been legitimately included according to the selection criteria. This may explain why the observed difference in mortality between treatment groups (13%) was less than expected and not statistically significant (95% confidence interval −8 to +33%). A trial of 15,000 to 20,000 patients would be required to obtain statistical significance for a difference of 13% with a placebo mortality rate of 5%.

In a recent review,[4] the pooled results (from 4,555 patients) given early treatment with intravenous and oral β blocker showed a 1-week mortality rate of 4.7% in control subjects compared with 4.3% for the β-blocker group, a difference of about 10%. From that pooled data, the upper 95% confidence limit was reported to be compatible with a 33% reduction in the odds of death; thus, it is in close agreement with the confidence limit of the MIAMI trial. In a recently published early intervention study of metoprolol in 800 patients from Belfast,[12] no significant difference in the in-hospital mortality rate was found between the placebo and metoprolol group, 5.2 vs 6.0%, respectively, with 95% confidence limits of −81 and +51%.

With a simple method, risk categories were defined using the unweighted combination of 8 risk predictors. With the presence of increasing numbers of risk predictors, the placebo mortality increased as did the difference between the death rates of the treatment groups. It appears that the study patients are composed of patients with a broad spectrum of mortality risk; most are at low risk that seems unaltered by metoprolol treatment after 15 days. It should be noted that the very high-mortality-risk patients were not included in this trial because the severity of their cardiovascular complications contraindicated treatment with a β blocker.

A multivariate analysis was necessary to quantitate the individual contribution of the risk predictors and to assess whether metoprolol's effect was influenced by these predictors.

It is likely that marked variations in mortality between centers and between countries will be found in a large multicenter trial. From the logit model it was found that geographic region had importance for prediction of mortality in addition to age, abnormalities on ECG and risk class based upon clinical history and status at entry. The lowest mortality was found outside Europe (Australia, New Zealand, Canada and Southeast Asia), while in Europe, Finland, Norway and Sweden had slightly higher odds for death than the rest of continental Europe and the United Kingdom.

The need to include geographic status to account for regional variations in mortality most likely indicates

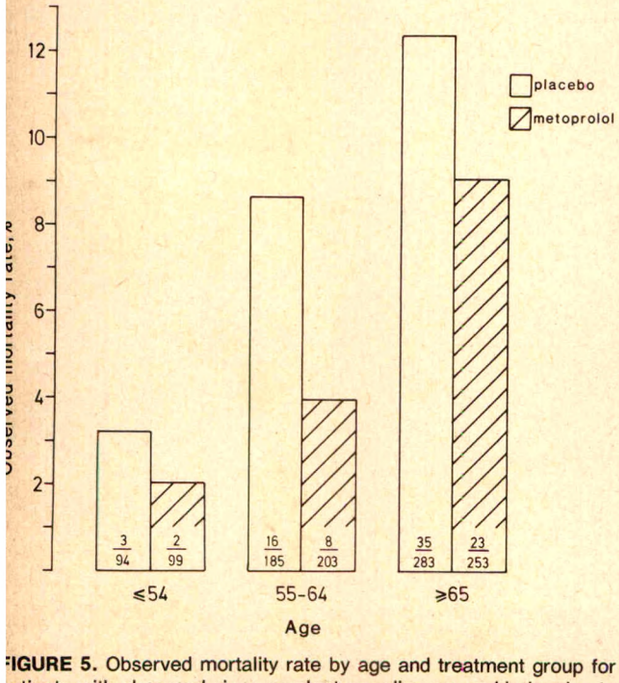

FIGURE 5. Observed mortality rate by age and treatment group for patients with abnormal signs on electrocardiogram and belonging to the high-risk class (see text).

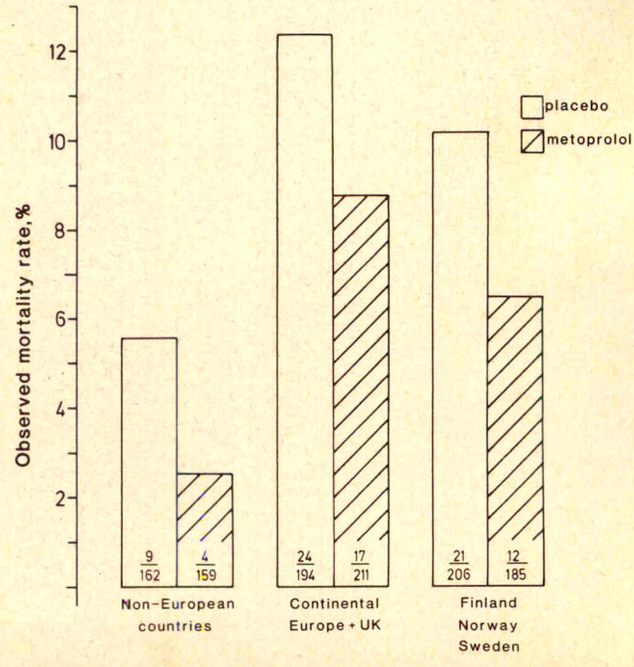

FIGURE 6. Observed mortality rate by geographic region and treatment group for patients with abnormal signs on electrocardiogram and belonging to the high-risk class (see text).

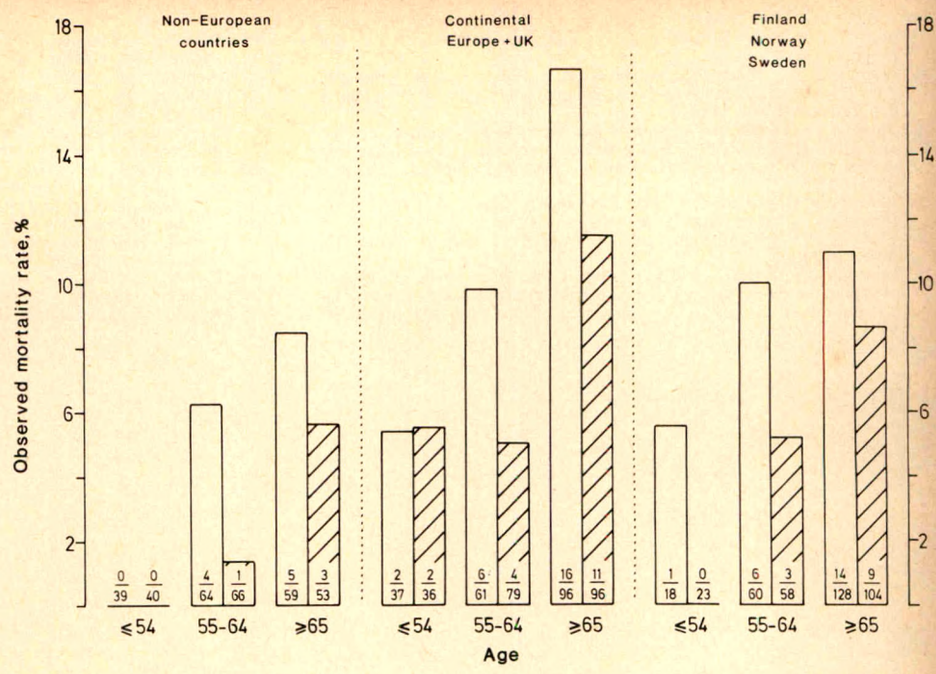

FIGURE 7. Observed mortality rate by age, geographic region and treatment group for patients with abnormal signs on electrocardiogram and belonging to the high-risk class (see text). □ = placebo; ▨ = metoprolol.

variations in patient selection between centers and regions that have not been adequately described by the baseline characteristics included in the model. This possibility will be explored further by examining the mortality among excluded patients in some representative centers.

The main indication from the logit model was that the effect of metoprolol was perhaps not uniform among the different risk classes defined from the patients' clinical history and status at entry. The observed difference in mortality in favor of metoprolol in the high-risk group was independent of age, signs on ECG at entry and geographic location of the patient. These findings are also consistent with results from other studies.

A beneficial effect among patients older than 60 to 65 has been observed for metoprolol in an early-intervention study[5,6] and for timolol, propranolol and metoprolol in late-intervention studies.[13–15] On the other hand, a tendency toward an increased mortality in patients older than 65 treated with β blockers has been suggested from an early-intervention study with alprenolol[16] and a late-entry study with oxprenolol.[17] The evidence from the present study—that patients with a history of cardiovascular disease or diabetes were at higher risk and achieved greater benefit—is in keeping with similar observations in other β-blocker postinfarction studies.[2,6,15,18,19]

The data from the MIAMI patient population obviously indicate a considerable heterogeneity in the distribution of baseline risk factors and associated mortality outcome. It is likely that this may be mainly explained by differences among centers in selection of trial patients.

One method of assessing the reproducibility of the previous Göteborg Metoprolol Trial would be to compare the patients of the 3 hospitals common to the 2 studies. The patients selected with MIAMI entry criteria from the Göteborg Metoprolol Trial showed a 7.0% placebo and a 3.8% metoprolol mortality rate after 15 days, a 45% difference (unpublished data). Similar results were obtained for all MIAMI patients recruited at these 3 hospitals: 9.9% placebo and 4.0% metoprolol mortality rates, a difference of 60%. The results obtained in these 3 hospitals were thus very similar in the 2 trials; they are also similar to those in the high-risk patients in the MIAMI trial.

It appears that early intervention with metoprolol in suspected myocardial infarction can achieve an early reduction in mortality, the magnitude of which is dependent upon the average death risk of the patient group.

Development of Myocardial Infarction

The MIAMI Trial Research Group

The effect of metoprolol on the development of an acute myocardial infarction (AMI) during days 0 to 3 and on late first and recurrent infarctions during days 4 to 15 has been investigated. Signs on electrocardiogram (ECG) were well balanced between the treatment groups at entry; 70% of patients had signs of suspected AMI and 19% of patients had normal ECGs. The remaining patients had abnormal ECGs but actual infarction could not be localized. The localization of suspected AMI was equivalently distributed in the 2 groups before randomization. Metoprolol altered the distribution of patients diagnosed during days 0 to 3 as having definite, possible or no AMI ($p < 0.02$). In the placebo group, there were more patients with definite AMI (72.5% vs 70.5%) and less with possible AMI (5.6% vs 7.4%) than in the metoprolol group. A larger proportion of patients developed a Q-wave infarction during days 0 to 3 in the placebo group (53.9%) compared with the metoprolol group (50.9%, $p = 0.024$). No difference in the effect of metoprolol regarding localization of the early AMI was observed. Late first myocardial infarction development (days 4 to 15) was observed in 20 patients (0.7%) in each group. Recurrent myocardial infarction tended to develop more frequently during days 4 to 15 in the placebo group compared with the metoprolol group (3.9% vs 3.0%, $p = 0.08$). In a multivariate analysis, delay time between onset of symptoms and randomization, signs on ECG at entry and metoprolol treatment were found to have a significant effect on the development of an AMI during days 0 to 3. Additionally, the delay time significantly influenced this effect of metoprolol. Metoprolol was found to decrease the risk of a definite AMI for patients treated early, while almost no effect was seen in patients treated more than 8 hours after onset of pain. In patients randomized early, the incidence of early AMI was particularly lowered in the metoprolol group among patients with heart rate, systolic blood pressure and rate pressure product higher than the median.

(Am J Cardiol 1985;56:23G–26G)

Upon hospital admission many patients with symptoms of acute myocardial infarction (AMI) have not yet developed clear-cut abnormalities on the electrocardiogram (ECG). A proportion of these patients may have arrived relatively early in the course of their infarction. Therefore, an appropriate intervention applied very soon after hospital arrival might prevent the infarct development.

The objectives of the present trial were to assess the incidence of definite AMI within 3 days, the incidence of late first myocardial infarction and recurrent myocardial infarction during the remaining trial period and the incidence of definite myocardial infarction during 5 and 15 days in patients with and without signs of infarction on the admission ECG. According to the protocol, subgroups were formed with respect to delay between onset of pain and blind injection, heart rate and suspected site of infarction before randomization.

Patients and Methods

The data from all randomized patients were analyzed. The diagnosis of infarction during days 0 to 3 was recorded as well as the type of diagnostic evidence and the site of infarction. The occurrence of a late first infarction or a recurrent infarction during days 4 to 5 and days 6 to 15 was also documented.[1]

Signs of AMI on ECG before randomization, including ST elevation, T-wave inversion or Q waves, were used to document the localization of myocardial infarction before trial injection in the same way as for the final diagnosis. The absence of all pathologic changes on ECG was noted as was the presence of pathologic changes, e.g., heart block and previous myocardial infarction, preventing further ECG classification. In addition to the subgroup analyses stated in the protocol, a number of subgroups were formed based on systolic blood pressure, rate-pressure product, pulmonary rales before trial injection, age and clinical history (previous myocardial infarction, angina pectoris and hypertension).

The general principles of statistical analysis were followed and have been described in a previous article in this issue.[1]

TABLE I Electrocardiogram (ECG) Findings of Suspected Acute Myocardial Infarction (AMI) Before Randomization

Results

Signs of suspected AMI on ECG before randomization were observed in 69.5% of the patients in the placebo group versus 70.9% in the metoprolol group. A similar proportion of patients in both groups (10.2% vs 10.5%) had an ECG with pathologic signs but actual infarction could not be localized. The localization of ECG abnormalities was equivalently distributed in the 2 groups before randomization (Table I).

Early acute myocardial infarction (days 0 to 3): The distribution of definite and possible AMI differed in the 2 groups ($p < 0.02$). In the placebo group the patients had more definite and less possible AMI than patients in the metoprolol group (Table II).

A larger proportion of patients developed a Q-wave infarction in the placebo group compared with the metoprolol group (53.9% vs 50.9%, $p = 0.024$, Table III). No difference regarding localization of the early AMI was observed.

Late first and recurrent myocardial infarction (days 4 to 15): Late first myocardial infarction development (days 4 to 15) was observed in 20 patients (0.7%) in each group. Recurrent myocardial infarction tended to develop more frequently during days 4 to 15 in the placebo group compared with the metoprolol group (3.9 vs 3.0%, $p = 0.08$).

Definite myocardial infarction (days 0 to 5 and days 0 to 15): During the first 5 days 72.6% of the patients in the placebo group versus 70.7% in the metoprolol group developed a definite myocardial infarction ($p = 0.12$). The number of patients developing myocardial infarction during days 0 to 15 was 73% versus 71.2% ($p = 0.12$, Table IV).

TABLE III Type and Site of Definite Acute Myocardial Infarction During Days 0 to 3

	Placebo		Metoprolol	
	%	n	%	n

TABLE IV Definite Myocardial Infarctions During Different Time Periods

	Placebo		Metoprolol	
	%	n	%	n
Days 0 to 5	72.6	2,106	70.7	2,035
Days 6 to 15	2.8	78	1.9	52
Days 0 to 15*	73.0	2,119	71.2	2,048

* A few patients developed myocardial infarctions on days 0 to 5 as well as days 6 to 15.

In patients with signs of suspected AMI on ECG before randomization, 88.4% in the placebo group compared with 84.4% in the metoprolol group developed myocardial infarction during days 0 to 5 ($p = 0.002$). Corresponding values for days 0 to 15 were 88.9% versus 85.6% ($p = 0.002$).

In patients without signs of suspected AMI on ECG before randomization, 30.4% in the placebo group compared with 26.5% in the metoprolol group developed myocardial infarction during the first 5 days ($p = 0.16$). Corresponding values for days 0 to 15 were 31.7% and 27.7%, respectively ($p = 0.14$).

Early acute myocardial infarction—univariate analysis: The incidence of definite AMI during days 0 to 3 was reduced by metoprolol treatment in patients randomized early after onset of symptoms, with higher entry heart rate, systolic blood pressure and rate-pressure product and signs of suspected AMI on ECG before randomization (Table V). A higher incidence of AMI was observed in the placebo group compared with the metoprolol group in the elderly (Table V). There was no indication that previous myocardial infarction, previous angina pectoris or previous hypertension were of importance.

In patients randomized within the median delay time, the incidence of early AMI was particularly lowered in the metoprolol group among patients with heart rate, systolic blood pressure and rate pressure product higher than the median (Table VI).

Early acute myocardial infarction—multivariate analysis: The possible predictors of development of a definite AMI within 3 days after blind injection were: infarct localization at entry ECG (anterior, inferior, other, pathologic and normal); delay from onset of pain to blind injection (<4, 4 to 8 and >8 hours); heart rate (<80, 80 to 90 and >90 beats/min); and drug (placebo and metoprolol). All these predictors except

heart rate were found to have significant effects on the odds for a definite AMI.

Metoprolol decreased the risk of a definite AMI for patients treated early, while almost no effect was seen for patients treated >8 hours after onset of pain ($p = 0.02$ for the test of interaction between drug and delay time; $p = 0.01$ for the test including both main drug effect and drug interaction with delay time). The risk for an AMI varied with signs at entry ECG (Table VII), but there was no significant interaction between the effect of metoprolol and ECG signs at entry.

Discussion

In most patients admitted to a coronary care unit with a strong suspicion of AMI, the infarction process has already started when they are regarded as suitable for intervention. In many patients Q waves appear within the first 2 hours after onset of symptoms.[2,3] However, for other patients there is a longer interval until abnormalities appear on the ECG.

Propranolol given to patients with threatening AMI without changes on ECG within 4 hours of onset of pain resulted in fewer completed infarctions.[4] Similar results have been reported for atenolol.[5]

In the Göteborg Metoprolol Trial there was no effect on the development of confirmed early AMI in all patients. In a retrospective subgroup analysis, the patients given metoprolol within 12 hours after the onset of pain and with a heart rate >70 beats/min before start of treatment were partly protected against development of AMI.[6]

Speculations regarding a protective role of long-term β blockade against the development of myocardial infarction were first reported in 1973.[7,8] In several trials evaluating the effect of long-term β blockade after myocardial infarction it has been shown that chronic β blockade reduces the incidence of nonfatal reinfarction.[9–13] In the Göteborg Metoprolol Trial, fewer patients developed a late myocardial infarction in the metoprolol group.[14] In other studies, no difference between treatment groups was detected.[15,16]

The present results indicate that metoprolol treatment may have transferred definite to possible AMI,

TABLE VII Observed Rates of Patients With Definite Acute Myocardial Infarction (AMI) Within 3 Days After Randomization and Expected Rates According to the Logit Model

		Signs on Electrocardiogram (ECG) Before Randomization

and similarly Q-wave to non–Q-wave myocardial infarction. Consequently it seems that treatment with metoprolol protected some patients from developing a definite Q-wave AMI.

The results from the univariate analyses are consistent with those of the previous study: patients with a high initial rate-pressure product were at greater risk of developing AMI, and metoprolol treatment had a more pronounced effect in these patients. Also, age seemed to be important to the results. However, when further evaluating the results in a multivariate model, delay from onset of symptoms to start of treatment was found to be the most important determinant of the protective effect of metoprolol against infarct development. The effect is mainly restricted to patients given the treatment <8 hours after onset of pain, and the most pronounced differences were observed in those patients with normal signs on ECG at entry—a group that constituted only 20% of the study sample.

The reduction in the number of Q-wave infarctions is in agreement with the concept of infarct size limitation. Recent studies also suggest that Q-wave infarctions have more complications and a worse prognosis than non–Q-wave infarctions.[17,18]

Enzymatic Estimation of Infarct Size

The MIAMI Trial Research Group

The maximum serum activity for aspartate aminotransferase (s-ASAT) during the first 3 days was recorded in 5,507 patients with suspected or definite acute myocardial infarction. The s-ASAT activity was corrected for the normal range from each center. The median s-ASAT activity was 4.9 arbitrary units in the placebo group versus 4.6 arbitrary units in the metoprolol group ($p = 0.072$). Univariate analyses indicated that the delay time between onset of symptoms and randomization and sympathetic activity at entry significantly influenced the effect of metoprolol. A similar decrease in serum enzyme activity after metoprolol treatment was observed independent of signs of infarct localization on the entry electrocardiogram.

(Am J Cardiol 1985;56:27G–29G)

The estimated infarct size is a major determinant for morbidity and mortality in acute myocardial infarction (AMI).[1–4] Different methods for assessing infarct size are available; they include analyses of serum enzyme activity,[5] precordial electrocardiographic mapping,[6] vectorcardiography[7] and radionuclide methods.[8] All these methods have disadvantages and none of them exactly reflects the infarct size. The maximum serum activity of enzymes, however, has been shown to quite closely reflect the size and the severity of the infarction.[1–4,9–11]

This article will describe the effect of metoprolol on serum enzyme activity. According to the protocol, subgroups were formed with respect to delay time, heart rate and site of suspected infarction at entry.

Patients and Methods

All patients in whom any of the enzymes used for infarct size estimation was analyzed were included in this study.

Blood samples were requested to be drawn according to local practice or at least once a day for days 0 to 3 to determine serum enzyme activity. It was requested that all centers should measure serum aspartate aminotransferase (s-ASAT) activity. The case report form allowed for recording of maximum assay results of s-ASAT, s-LD (lactate dehydrogenase), s-LD1 (isoenzyme 1), s-CK (creatine kinase), s-CK MB and s-CK B. Data were recorded as either international units/liter or μkat/liter. A factor of 60 was used to convert μkat/liter to international units. Because routine local methods were used for enzyme analyses, great differences in numerical values of the enzyme activities were expected, mainly owing to different reaction temperatures (25 to 37°C). The upper and lower limits of the normal range for each enzyme were recorded in all centers. Enzyme activity was therefore transformed to a corrected value (arbitrary unit, [a.u.]). A linear correction was obtained by dividing the difference of the individual serum activity and the midpoint of the local normal range by the midpoint of the local normal range.

Because s-ASAT was the enzyme analyzed in almost all centers, this article will mainly deal with this enzyme. Overall results will also be reported for the other enzymes, with exceptions for LD and LD1, which were studied in a subgroup of patients in an optional study and will be reported elsewhere.

In addition to the subgroup analyses stated in the protocol, a number of subgroups were formed based on systolic blood pressure, rate-pressure product, pulmonary rales, age and clinical history (myocardial infarction, angina pectoris and hypertension).

Statistical analyses: The general principles of statistical analysis were followed. Because only maximum serum activity was documented, it was considered inappropriate to conduct a detailed multivariate analysis to assess the influence of various baseline variables on the effect of metoprolol. Instead, pertinent subgroups are presented for descriptive purposes.

Results

Maximum serum activity for s-ASAT was recorded in 95% of patients with suspected or definite AMI. Corresponding figures for s-CK, s-CK MB and s-CK B were 75%, 20% and 14%, respectively. A lower median serum enzyme activity was observed in the metoprolol

TABLE IV Maximum s-ASAT Activity in Relation to Findings on Electrocardiogram (ECG) Before Blind Injection

		Placebo	Metoprolol
ECG Before Blind Injection	n	Median a.u.	Median a.u.
No signs of AMI	1,090	0.6	0.6
Signs of AMI	3,835	7.4	6.8
Anterior AMI	1,824	7.8	7.5
Inferior AMI	1,498	7.8	6.8
Other AMI	513	5.0	4.0
Pure anterior AMI	1,360	7.3	6.7
Pure inferior AMI	1,212	7.8	6.6

AMI = acute myocardial infarction; a.u. = arbitrary unit.

group compared with placebo for all enzymes (Table I). The median s-ASAT activity was 4.9 a.u. in the placebo group versus 4.6 a.u. in the metoprolol group ($p = 0.072$).

In patients entered within the median delay time (7 hours), the reduction in serum enzyme activity after metoprolol treatment was more substantial ($p = 0.026$, Table II).

Among all randomized patients initial heart rate did not appear to have a pronounced influence on the effect of metoprolol treatment on s-ASAT activity ($p = 0.12$, Table II). In patients with a systolic blood pressure higher than the median (140 mm Hg), s-ASAT activity was lower in the metoprolol group compared with the placebo group ($p < 0.001$, Table II). In patients with a rate-pressure product higher than the median before randomization, s-ASAT activity was higher in the placebo group compared with the metoprolol group ($p < 0.001$, Table II).

Among patients randomized within the median delay time (7 hours) and with heart rate, systolic blood pressure or rate-pressure product higher than the median at entry, enzyme activity after metoprolol treatment was significantly decreased compared with placebo ($p = 0.026$, $p = 0.005$ and $p < 0.001$, respectively, Table III).

In patients with signs of suspected AMI on electrocardiogram before randomization, s-ASAT activity was higher in the placebo group compared with the metoprolol group ($p < 0.001$, Table IV). A similar decrease in serum enzyme activity after metoprolol treatment was observed independent of infarct localization before randomization (Table IV).

Among patients who developed definite AMI, s-ASAT activity tended to be higher in the placebo group compared with the metoprolol group ($p = 0.10$, Table V).

In patients older than the median age, the serum enzyme activity was higher (5.4 a.u.) in the placebo group compared with the metoprolol group (4.7 a.u., $p < 0.010$).

Discussion

The hypothesis that β blockade may limit indexes of infarct size in man has been tested. Intravenous β blockers given early in the course of AMI have resulted in a reduction of ST-segment elevation and relief of chest pain.[12–14] In later, large, randomized trials β blockade given within a few hours after the onset of pain has consistently lowered serum enzyme activity;[15–21] in contrast, treatment started later has had no effect.[15–17,20] In some studies, independent electrocardiographic registrations have supported these findings.[17,18] In a recent propranolol study in AMI, no reduction in infarct size was detected perhaps because too few patients were included early.[22] In that same study[22] there was a tendency for a positive effect of propranolol in patients treated within 8 hours of onset of symptoms of AMI.

TABLE V Maximum s-ASAT Activity in Relation to Final Acute Myocardial Infarction (AMI) Diagnosis Days 0 to 3

		Placebo	Metoprolol
	n	Median a.u.	Median a.u.
No AMI	1,233	0.3	0.3
Possible AMI	360	0.4	0.6
Definite AMI	3,914	7.8	7.4

a.u.= arbitrary unit.

Different enzyme analyses were performed in the MIAMI trial according to the local practice in each center. In 95% of all participating patients, the maximum activity of s-ASAT was recorded and, therefore, all results in the various subgroup analyses performed have been presented for this enzyme. One major disadvantage of using s-ASAT activity as an indirect measurement of infarct size is its lack of specificity. This might have underestimated the true effect of metoprolol. The reduction in serum enzyme activity, expressed in percentage, seemed to be higher when more heart-specific enzymes such as s-CK MB or s-CK B were analyzed.

The findings of this study are compatible with other studies, even though the overall effect on serum enzyme activity in all patients lacked pronounced statistical significance. They are also compatible with the findings of a study on infarct development,[23] in which delay time had an important influence on the effect of metoprolol. The reduction in serum enzyme activity appeared to be restricted to patients treated shortly after the onset of suspected infarction.

In the previously reported Göteborg Metoprolol Trial[24] the prerandomization heart rate and rate-pressure product were of importance. These findings were corroborated in this study. In addition the present study showed a reduction in serum enzyme activity in patients with a high systolic blood pressure.

The better reduction of serum enzyme activity among patients with signs of infarction on the electrocardiogram at the time of randomization might be explained by several factors. In the group of patients with no signs of AMI on ECG there were probably several patients with no ischemic heart disease. In the present study, infarct localization did not appear to influence the effect of metoprolol on enzyme levels.

When the present results are considered and related to our previous report[17] and reports from other groups,[15,16,18] it must be concluded that early treatment with metoprolol limits enzymatically estimated infarct size and that the magnitude of this effect is strongly influenced by the time between onset of symptoms and start of treatment.

Narcotic Analgesics and Other Antianginal Drugs

The MIAMI Trial Research Group

The effect of metoprolol on chest pain has been assessed in terms of the duration and the use of narcotic analgesics, nitrates and calcium-channel blockers. Fewer metoprolol-treated patients in the MIAMI trial were given narcotic analgesics (49% of the placebo patients vs 44% of the metoprolol patients, $p < 0.001$), nitrates (55% vs 53%, $p = 0.10$) and calcium-channel blockers (12% vs 9%, $p < 0.001$). A total number of 6,697 dose equivalents of narcotic analgesics were given to the placebo group compared with 5,493 dose equivalents to the metoprolol group, a difference of 18% ($p < 0.001$). Mean dose equivalents were 2.3 and 1.9, respectively. The analysis of the total use of the 3 types of treatment for ischemic chest pain showed a significantly less frequent use of treatment for chest pain in the metoprolol group than in the placebo group ($p < 0.004$). The relative difference in the incidence of drug treatment tended to be more striking for patients with maximal therapy, i.e., receiving high doses of narcotic analgesics, nitrates and calcium-channel blockers. There were 22% fewer patients receiving 4 or more doses of narcotic analgesics in the metoprolol group than in the placebo group. A multivariate analysis disclosed that site of suspected infarction, delay time, entry systolic blood pressure and metoprolol treatment all had a significant effect on the use of narcotic analgesics. There was a nonsignificant tendency for heart rate to be of importance. In the placebo group the use of narcotic analgesics increased with decreasing delay time and increasing systolic blood pressure. The use was highest for patients with signs of anterior infarction on electrocardiogram (ECG) and lowest for patients with normal ECG at entry. The effect of metoprolol was independent of delay time and systolic blood pressure but varied with ECG classification. The highest effect was seen among patients with signs of anterior infarction.

(Am J Cardiol 1985;56:30G–34G)

A variety of pharmacologic and other measures have been used to control chest pain in acute myocardial infarction (AMI) ranging from analgesics or tranquilizers[1] to drugs that act mainly through direct or indirect effect on the ischemic myocardium.[2] Persistent or recurrent chest pain may induce adverse systemic and coronary circulatory effects via autonomic reflexes, mediated via sympathetic efferent nerves,[3] but also to some degree via the vagal nerve.[4]

In order to relieve pain, very large doses of morphine-like drugs are sometimes required that may themselves induce unfavorable effects.[5–7] Additional approaches to pain control in AMI are therefore desirable. Earlier studies have suggested the beneficial effect of metoprolol both in prevention of ischemic chest pain and treatment of pain.[8–10]

The aim of the present analysis was to assess the effect of metoprolol compared with placebo on chest pain as reflected by the duration of treatment with narcotic analgesics, use of analgesics, nitrates and calcium-channel blockers. According to the protocol, subgroups were formed with respect to delay time, heart rate and site of infarction.

Address for reprints: Åke Hjalmarson, MD, Department of Medicine I, Sahlgren's Hospital, S-413 45, Göteborg, Sweden.

Patients and Methods

All patients (n = 5,778) were included in the analysis. Pain as such was not measured directly. Instead, the usage and number of doses of narcotic analgesics were used as markers of chest pain, as well as the use of nitrates and calcium-channel blockers. One dose equivalent of any narcotic analgesic was defined as the dose equipotent to the analgesic effect of 5 mg of morphine. The duration of pain was defined as the time in hours from randomization to the time of injection of the last dose of narcotic analgesic. This could only be measured during days 0 to 5.

In addition to the subgroup analyses stated in the protocol, a number of subgroups were formed based on systolic blood pressure, rate-pressure product, age, sex, diuretic usage and heart failure.

Statistical methods: The general principles of statistical analysis were followed.[11]

A univariate analysis was performed to see whether there was any influence of the variables defining the subgroups on the use of narcotic analgesics.

An analysis was undertaken of the effect of metoprolol on the combined use of nitrates, calcium-channel blockers and single and multiple doses of narcotic analgesics. Narcotic analgesics were considered the strongest and 3 levels were used (no analgesics, 1 to 3 dose equivalents of analgesics and 4 or more dose equivalents of analgesics). Because nitrates could be and were used freely during the entire trial period, calcium-channel blockers were considered "stronger" than nitrates (drug given or not given). Nitrates were ranked lowest and 2 levels were again used (given or not given). Consequently, 12 classes were constructed to describe different strengths of antianginal and analgesic treatment and perhaps reflect different degrees of ischemic chest pain. In this analysis, the distribution of patients over the 12 classes is described graphically in the 2 treatment groups, and the difference between the treatment groups in these distributions was tested.[12] A difference in the distribution between treatment groups would reflect a difference in the combined use of antianginal drugs and hence may suggest an effect on chest pain by metoprolol.

In addition a multivariate model was applied to analyze the importance of different factors for the development of chest pain requiring treatment with narcotic analgesics.

In a logit model, the influence of the following factors on the odds that a patient will be treated with a narcotic analgesic during days 0 to 15 was analyzed: electrocardiogram (ECG) on admission (anterior infarction, inferior infarction, other locations, pathologic but localization not possible and no abnormalities), delay time from onset of chest pain to randomization (<4, 4 to 8 and >8 hours), heart rate (<80, 80 to 90 and >90 beats/min), systolic blood pressure on admission (<140, 140 to 160 and >160 mm Hg) and drug (placebo or metoprolol).

Results

Narcotic analgesics were given to 49.4% of the patients in the placebo group compared with 44.1% in the metoprolol group, a difference of 11% ($p < 0.001$). Nitrates were given to 55.3% in the placebo group compared with 53.1% in the metoprolol group ($p = 0.10$). Calcium-channel blockers were used more often in the placebo group (11.8%) than in the metoprolol group (8.8%), a difference of 25% ($p < 0.001$, Fig. 1).

The total number of dose equivalents of narcotic analgesics during days 0 to 15 differed by 18% ($p < 0.001$) between the placebo group ($n = 6,697$) and the metoprolol group ($n = 5,493$). A mean of 2.31 dose equivalents/patient was given to the placebo group compared with 1.91 in the metoprolol group during days 0 to 15 ($p < 0.001$).

Among patients to whom narcotic analgesics had actually been given during days 0 to 15, the mean dose equivalents were 4.69 in the placebo compared with 4.32 in the metoprolol group, a difference of 8% ($p = 0.05$).

The total pain duration differed by 17% ($p < 0.001$) between the placebo group (42,935 hours) and the metoprolol group (35,675 hours). Mean duration of pain for the placebo group was 14.8 hours compared with 12.4 hours for the metoprolol group ($p < 0.001$). When only the patients who had received narcotic analgesics were analyzed, no difference in mean pain duration was found; it was 30.8 hours for the placebo group compared with 29.2 hours for the metoprolol group ($p < 0.2$).

Among patients with entry heart rates higher than the median (80 beats/min), narcotic analgesics were given to 52.2% in the placebo group compared with 43.9% in the metoprolol group, a difference of 16% ($p < 0.001$, Fig. 2) and the mean dose equivalents in the placebo group were 2.51 compared with 2.0 in the metoprolol group, a difference of 20% ($p < 0.001$, Fig. 3).

For patients with entry systolic blood pressure higher than the median (140 mm Hg) the percentage use of narcotic analgesics was 54% in the placebo group compared with 44.8% in the metoprolol group, a difference of 17% ($p < 0.01$, Fig. 2) and the mean dose equivalents were 2.64 and 2.0, respectively, a difference of 24% ($p < 0.001$, Fig. 3).

The influence of rate-pressure product on the use of narcotic analgesics revealed a similar pattern in the 2 treatment groups.

In all the remaining subgroups of patients in whom entry heart rate, systolic blood pressure or rate-pressure product was lower than the median, there was a consistently less pronounced and nonsignificant difference in favor of metoprolol between the treatment groups for all variables (Fig. 2 and 3).

Neither age, sex nor acute heart failure on admission, defined as administration of diuretics before randomization, had any association with the use of narcotic analgesics.

The analysis of the total use of the 3 types of treatment for ischemic chest pain showed a significantly different distribution in the 2 treatment groups ($p < 0.004$). The difference in the percentage use of drug

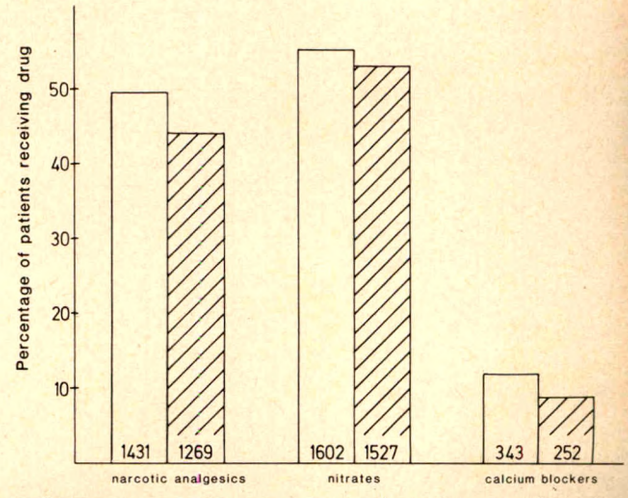

FIGURE 1. Number and percentage of patients given narcotic analgesics, nitrates and calcium-channel blockers during days 0 to 15. □ = placebo patients; ▨ = metoprolol patients.

treatment tended to be more pronounced for patients with maximal therapy, i.e., those receiving high doses of narcotic analgesics, nitrates and calcium-channel blockers. Although this was only a small group, 42% fewer patients received the maximal treatment in the metoprolol group compared with placebo (Fig. 4). The difference for all patients receiving 4 or more doses of narcotic analgesics, constituting one-fourth of all placebo patients, was 22%. Thus, patients who seem to benefit most from metoprolol are those who suffered the most pain, as reflected by the high use of narcotic analgesics with or without combined treatment with nitrates and calcium-channel blockers.

The multivariate analysis disclosed that site of infarction, delay time and systolic blood pressure had a significant effect on the use of narcotic analgesics. There was a nonsignificant tendency for heart rate to be of importance.

In the placebo group the use of narcotic analgesics increased with decreasing delay time and increasing systolic blood pressure. Furthermore, the use was most frequent for patients with signs of anterior infarction on ECG and lowest for patients with normal ECG.

The drug effect did not vary significantly with delay time and systolic blood pressure, but varied significantly with ECG classification at entry. The highest effect was seen among patients with signs of anterior infarction. For patients with signs on ECG classified as "inferior", "pathological" or "normal", only a minor drug effect was observed (Table I).

Discussion

The present MIAMI trial confirmed previous findings of a reduced use of narcotic analgesics in the early

phase of myocardial infarction after treatment with metoprolol.[9,10]

Although incidence and intensity of pain were not directly measured in the present trial, the amount of analgesics and the time span over which they were given undoubtedly reflect the intensity and duration of ischemic chest pain. The fact that a positive effect on chest pain could be detected even though more than half of the placebo patients were given nitrates is important because nitrates have been shown to be effective for pain control in AMI.[13] In fact there was a trend to less use of nitrates, as well as a significant reduction in the use of calcium-channel blockers, in the metoprolol group. This reflects a reduction in the incidence of a low degree of pain for which these drugs are used. The decreased usage of narcotic analgesics in the metoprolol group indicates that recurrent chest pain was prevented. The lower mean dose of narcotic analgesics among those patients receiving analgesics also indicates that pain intensity may have been reduced by metoprolol.

In patients with acute heart failure a worsening of chest pain may have been anticipated after metoprolol, as further dilatation of the ventricle may increase myocardial oxygen consumption. The effect of increase in wall tension on myocardial oxygen consumption may, however, have been counteracted by the pronounced reduction in rate-pressure product. Therefore, there is no support from the present trial for the proposal that AMI patients with chest pain and mild heart failure should be treated with nitrates in preference to metoprolol. Patients with high heart rate and blood pressure at entry seemed to respond more favorably than those with low heart rate and blood pressure. However, a selection of patients with heart rate >65 beats/min for the trial may have obscured the true importance of heart rate. An interesting finding is that heart rate does not seem to be a strong determinant of the drug effect according to the multivariate analysis. The more pronounced benefit in patients with anterior infarction may be due to the fact that they seem to have more pain (higher usage of narcotic analgesics) (Table I) and to have higher heart rates compared with those with inferior infarction. The analysis does not exclude the possibility that metoprolol might be effective in patients with inferior infarction and high heart rates.

Metoprolol was effective in patients admitted with short as well as long delay after onset of chest pain, even though the intensity of chest pain was more pronounced in patients arriving early (Table I). Metoprolol seems to be of special value for pain control in patients with severe and prolonged pain. It also seems that metoprolol has a pain-relieving effect additional to nitrates and calcium-channel blockers.

The additional effect of metoprolol in patients given nitrates may be because nitrates mainly affect blood pressure. An increase in heart rate may occur after treatment with nitrates in patients with left-sided heart failure.[13,14] Similar effects are seen after calcium-channel blockers.[15,16] Reduction of blood pressure is therefore common for all 3 drugs; a fall in heart rate is only seen after metoprolol.

Prevention and reduction of chest pain in patients with AMI or impending infarction seem to be parallel

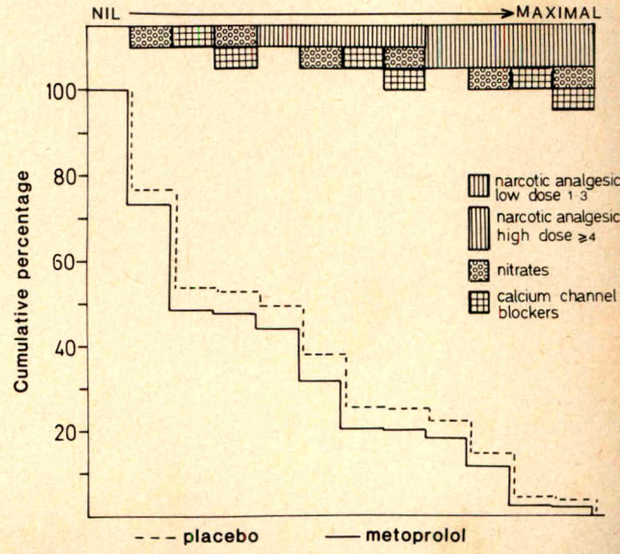

FIGURE 4. Cumulative distribution curve of combined treatment with narcotic analgesics, nitrates and calcium-channel blockers in all patients during days 0 to 15.

to prevention of infarct development[17] and reduction of indexes of size of infarction.[18] Pain abolition may be mediated through common pathways.

Arrhythmias

The MIAMI Trial Research Group

Forty-five patients in the placebo (1.5%) and 29 in the metoprolol (1%) groups, respectively, were receiving antiarrhythmic drugs on a long-term basis before entry into the trial. Before randomization, 2.2% (n = 64) of the placebo and 1.7% (n = 50) of the metoprolol patients developed ventricular fibrillation (VF) in the hospital. The corresponding figures for atrial fibrillation or flutter were 3% (n = 87) and 3.3% (n = 94). After randomization, there was no significant difference in the number of patients who developed VF in the placebo (n = 52) and the metoprolol (n = 48) groups. The total number of episodes of VF tended to be fewer in the metoprolol group (n = 67) compared with the placebo group (n = 96). The tendency was, however, not apparent until after 5 days. When the occurence of VF was related to high- and low-mortality risk groups, any beneficial effect of metoprolol was confined mainly to the high-risk group. A similar proportion of patients underwent electric conversion for ventricular tachyarrhythmia in the 2 groups. Although antiarrhythmic drugs were intended to be given only for major ventricular tachyarrhythmias a large proportion of patients received such treatment. Significantly more patients were treated with antiarrhythmics in the placebo (21.5%) than in the metoprolol group (19.2%, p = 0.03) during the study period, but predominantly during the first 5 days. Atrial fibrillation or flutter and other supraventricular tachyarrhythmias were significantly less frequent in the metoprolol than in the placebo group, as was the use of cardiac glycosides. The sum of patients who had a nonfatal VF or who died during days 0 to 5 was not different between the treatment groups.

(Am J Cardiol 1985;56:35G–38G)

The introduction of coronary care units has decreased mortality in acute myocardial infarction (AMI) largely because of effective treatment of ventricular fibrillation (VF) and prophylaxis against VF and prolonged attacks of ventricular tachycardia (VT) as well as other arrhythmias.

One of the secondary objectives of the MIAMI trial was to assess the effect of metoprolol on VF. Besides VF other types of tachyarrhythmias and bradyarrhythmias were also studied. The influence of metoprolol on the occurrence of these arrhythmias is reported in this article.

According to the protocol the aim was to study the incidence of VF together with the sum of deaths and nonfatal VF during the first 5 days in the placebo and metoprolol groups. Further, the occurence of VT, atrioventricular block, atrial fibrillation and other supraventricular tachycardia and the use of digitalis and antiarrhythmic agents are reported.

Patients and Methods

All randomized patients were included. In patients with VF, the date and time of each episode were recorded. Before breaking the trial code, episodes of VF obviously induced by such iatrogenic procedures as cardiac catheterization and open-heart surgery were omitted from the analysis. Similarly, agonal VF, defined as VF in association with refractory cardiogenic shock or pulmonary edema, was not included in the analysis. Consequently, the analysis includes both patients with primary and secondary VF, but it was not possible to separate these 2 types.

Ventricular tachycardia: The MIAMI manual of procedures recommended that VT should be treated immediately if it markedly influenced hemodynamics or caused symptoms but otherwise only if it was sustained for more than 30 seconds. DC conversion was always to be performed initially for rapid treatment of VT and VF. Thereafter treatment with lidocaine was suggested. The drug was to be administered according to a dosage schedule outlined in the manual of procedures (75 mg intravenously as a bolus dose followed by intravenous infusion of 4 mg/min during 3 hours. Thereafter the infusion rate should be reduced to 2 to 3 mg/min). It was suggested that ventricular ectopic beats were not to be treated unless they caused signs of impaired cardiac function, e.g., hypotension or heart failure, or if they caused subjective discomfort. It was recommended that all other antiarrhythmic agents should be avoided.

Supraventricular arrhythmias: Two categories were recorded, atrial fibrillation or flutter and other supraventricular tachycardia (rate exceeding 120 beats/min). The last category could be either an ectopic supraventricular tachycardia or a sinus tachycardia.

Address for reprints: Åke Hjalmarson, MD, Department of Medicine I, Sahlgren's Hospital, S-413 45, Göteborg, Sweden.

Atrioventricular blocks and asystole: First-degree atrioventricular block was recorded when the conduction time exceeded 0.26 seconds and asystole was defined as asystole necessitating treatment.

Antiarrhythmic agents: The use of cardiac glycosides and antiarrhythmic drugs was recorded for days 0 to 5 and 6 to 15 of the trial period.

The MIAMI manual of procedures contained advice concerning treatment. Digitalis was recommended for supraventricular tachyarrhythmias if the ventricular rate exceeded 120 beats/min or if there were frequent atrial ectopics or recurrent atrial fibrillation or flutter. DC conversion was to be used when indicated. According to local practice, verapamil could be cautiously given intravenously and orally in patients without heart failure. The use of digitalis was not separated according to whether this drug had been used for heart failure or tachyarrhythmia. It was recommended that digitalis be avoided for the treatment of heart failure in patients with sinus rhythm. It was suggested that other antiarrhythmic agents be restricted only to symptomatically or hemodynamically important supraventricular or ventricular arrhythmias or after VF.

Results

Forty-five patients in the placebo (1.5%) and 29 in the metoprolol (1%) groups were on long-term therapy with antiarrhythmic drugs before entry into the trial. Before randomization 2.2% (n = 64) of the placebo and 1.7% (n = 50) of the metoprolol patients developed in-hospital VF. The corresponding figures for atrial fibrillation or flutter were 3% (n = 87) and 3.3% (n = 94). The median delay time between onset of symptoms and randomization in both groups was between 6 and 7 hours and the mean delay time was 8.6 hours.

Ventricular fibrillation and tachycardia: VF was reported in 132 patients. In 2 of these patients it was iatrogenically induced and in 30 patients, only agonal episodes were noted. These 32 patients were excluded from the analysis. Thus, the remaining number of patients with VF was 100; of these, 52 (1.8%) belonged to the placebo and 48 (1.7%) to the metoprolol group (Fig. 1). The total number of episodes of VF was somewhat lower in the metoprolol group (n = 67) compared with the placebo group (n = 96), but this difference was not significant statistically and the tendency was only apparent during days 6 to 15. During this time period 54 episodes of VF occurred in the placebo group and 24 in the metoprolol group (Fig. 2).

Both the number of patients with VF and total number of episodes of VF have been analyzed for low- and high-risk patients defined in Table VI in a previous article in this issue.[1] Among the low-risk patients there was no difference between the treatment groups; a tendency towards a lower number of episodes of VF was apparent among high-risk patients in the metoprolol compared with the placebo group (Fig. 3). The patients on a full dose of metoprolol tended to have a lower incidence of VF compared with placebo (Fig. 4).

Electrically converted VT occurred among 1.4% (n = 40) of the placebo and 1.3% (n = 37) of the metoprolol patients (Table I).

Deaths and nonfatal ventricular fibrillation, days 0 to 5: The number of patients who died or had a

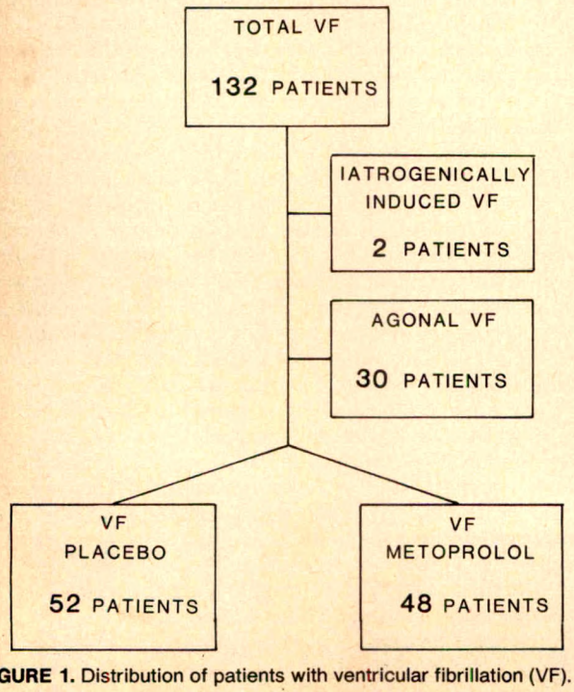

FIGURE 1. Distribution of patients with ventricular fibrillation (VF).

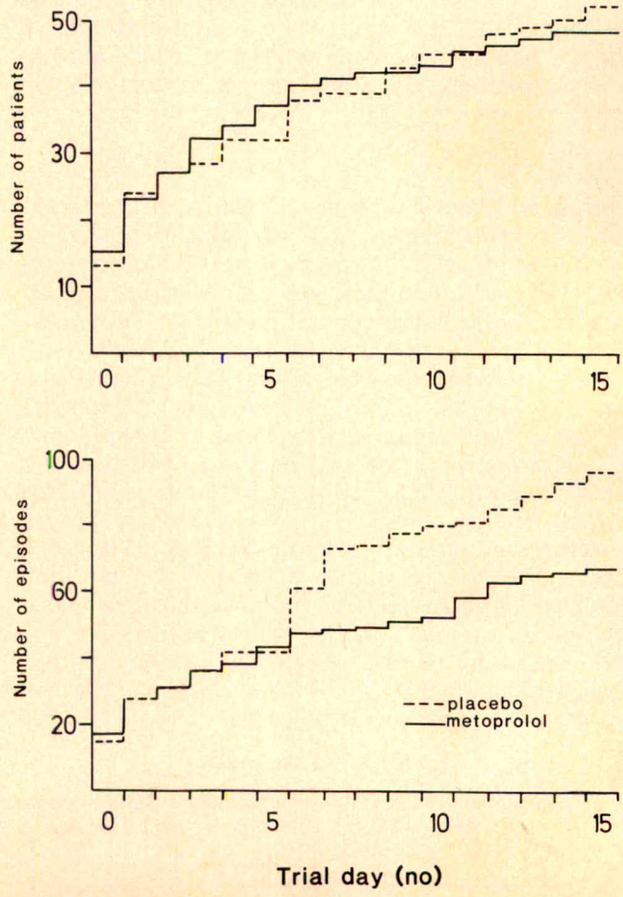

FIGURE 2. Cumulative number of patients with ventricular fibrillation (VF) and episodes of VF after randomization during the study period.

nonfatal VF was 110 in the placebo and 100 in the metoprolol group, a difference that was not significant statistically.

Supraventricular tachyarrhythmias: There was a lower number of patients with atrial fibrillation or flutter in the metoprolol group during days 0 to 15 ($p = 0.010$) and days 0 to 5 ($p = 0.017$) (Table I, Fig. 5). The reduction of other supraventricular tachycardias was also pronounced during both time periods ($p < 0.001$) (Table I, Fig. 6).

Bradyarrhythmias: Slightly more patients developed first-degree atrioventricular block in the metoprolol group during the early phase ($p = 0.028$) and there was a tendency still evident when the whole study period (days 0 to 15) was considered ($p = 0.075$). No difference was observed between the 2 groups for atrioventricular block II to III or asystole necessitating treatment (Table I).

Use of antiarrhythmic drugs: Antiarrhythmic agents were widely used, in particular during days 0 to 5, despite the recommendations in the manual of procedures. Antiarrhythmic drugs tended to be used more often in the placebo patients (19.7%) than in the metoprolol patients (17.9%) during days 0 to 5 ($p = 0.09$). The corresponding figures for days 0 to 15 were similar (Table I), and the difference for this period was significant ($p = 0.03$). There was a lower use ($p < 0.001$) of digitalis in the metoprolol patients (13.6%) compared with placebo patients (16.6%) during the whole study period and during days 0 to 5 (10.6 vs 14.2%, respectively) (Table I).

TABLE I Arrhythmic Events and Use of Antiarrhythmic Therapy During the Trial Period

Time Period (days)	Events/Use of Drugs	% Pts (no. of pts) with Event/Use of Drugs: Placebo	Metoprolol
0 to 15	VT, electrically converted	1.4 (40)	1.3 (37)
	Asystole, treated	2.2 (64)	2.6 (74)
	AV block I	2.5 (72)	3.3 (95)
	AV block II to III	5.3 (153)	5.6 (160)
	Atrial fibrillation/flutter	10.3 (298)	8.3 (238)
	Other SVT (>120 beats/min)	9.1 (265)	4.4 (125)
	Antiarrhythmics	21.5 (624)	19.2 (552)
	Cardiac glycosides	16.6 (482)	13.6 (391)
0 to 5	VT, electrically converted	1.0 (28)	1.0 (30)
	Asystole, treated	1.8 (51)	2.1 (61)
	AV block I	2.1 (62)	3.1 (89)
	AV block II to III	4.7 (137)	5.3 (153)
	Atrial fibrillation/flutter	9.2 (268)	7.5 (215)
	Other SVT (>120 beats/min)	8.2 (238)	3.9 (106)
	Antiarrhythmics	19.7 (572)	17.9 (516)
	Cardiac glycosides	14.2 (411)	10.6 (304)

AV = atrioventricular; SVT = supraventricular tachycardia; VT = ventricular tachycardia.

Discussion

The 2 groups were seemingly well balanced in terms of factors of particular importance for the arrhythmia analyses, i.e., proportion of patients with arrhythmias and treatment with antiarrhythmic agents before randomization. However, it should be noted that there were 14 patients more in the placebo group who had prerandomization VF. It was most likely that these patients entered the trial receiving lidocaine prophylaxis, and thus may have introduced some imbalance in the 2 major treatment groups at randomization.

The lack of a significant effect of metoprolol on the occurrence of VF and VT is in contrast with previous findings of a prophylactic effect of metoprolol against VF in early myocardial infarction.[2] It also contrasts a recent report on the prevention of VF during AMI by intravenous followed by oral propranolol.[3] In the Göteborg Metoprolol Trial, both the number of patients and the number of episodes of VF and the number of patients with VT were less common among metoprolol-treated patients.[4] Serious ventricular arrhythmias in AMI have also been decreased by atenolol[5] and alprenolol.[6]

There are important differences between the Göteborg Metoprolol Trial and the present investigation.

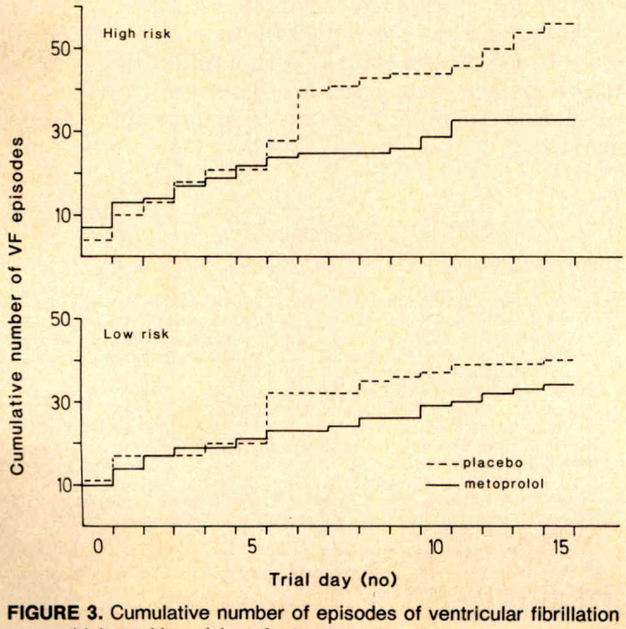

FIGURE 3. Cumulative number of episodes of ventricular fibrillation among high- and low-risk patients.

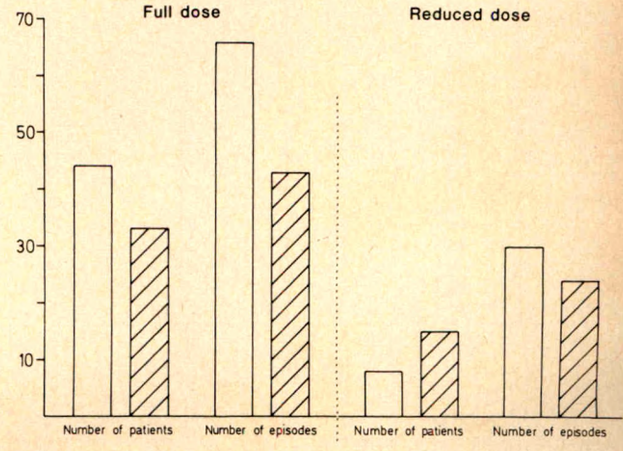

FIGURE 4. Distribution of ventricular fibrillation related to administration of trial drug.

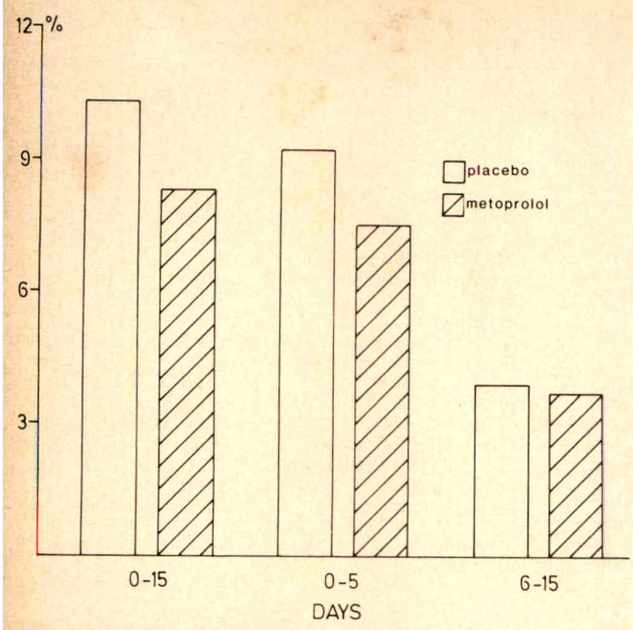

FIGURE 5. The proportion of patients with atrial fibrillation or flutter.

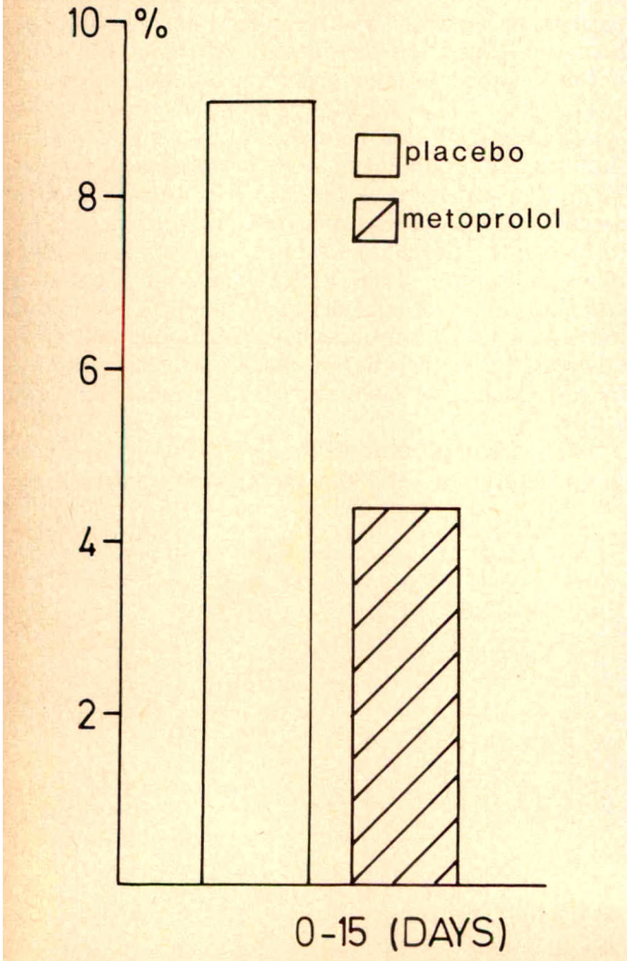

FIGURE 6. The proportion of patients with other supraventricular tachycardias (rate >120 beats/min).

The Göteborg Metoprolol Trial[2,4] included patients already on long-term β blockade. In that trial it was shown that the effect on VF was primarily on events occurring late, and the same tendency is apparent in the present trial. An effect against VF may depend more on protection against myocardial ischemia rather than on a direct electrophysiologic antifibrillatory effect. Patients already on long-term β blockade supplemented by an extra intravenous dose may become more rapidly protected than patients in whom treatment has just been started. Another reason for discrepancies between these 2 studies would be the induction of VF through discontinuation of previous β-blocking agents rather than protection through the institution of test drug. The results of the Göteborg Metoprolol Trial do not support such a conclusion, because the main reduction of VF occurred among patients not previously receiving β blockers. However, this concept is supported by another study,[3] which indicated that the protective effect of propranolol against VF within 48 hours was more pronounced in patients who had received previous β blockade. There was a remarkably high frequency (8%) of VF in those patients on previous β blockade who were randomized to the control group.

Another perhaps more important observation is the frequent use of antiarrhythmic drugs in the present trial. In the Göteborg Metoprolol Trial, lidocaine was given to only 5.5% of the placebo and 2.3% of the metoprolol patients during the complete initial hospitalization, which averaged 11 days. In the present study almost 20% of patients had received antiarrhythmic drugs during the first 5 days. It is difficult to explain the extensive use of such drugs at some hospitals without suspecting either treatment of a high number of benign ventricular arrhythmias or a prophylactic usage. The widespread usage of such drugs interferes with the possibility of testing the antifibrillatory potency of metoprolol.

A reduced incidence of supraventricular tachyarrhythmias and the use of digitalis among the metoprolol-treated patients support earlier reports.[4] The finding of no increase in asystole or important conduction disturbances supports the use of metoprolol as a safe agent.

Other Clinical Findings and Tolerability

The MIAMI Trial Research Group

Fifteen minutes after injection there was a fall in mean heart rate (18%, p <0.001), systolic blood pressure (10%, p <0.001) and rate-pressure product (27%, p <0.0001) in the metoprolol group of patients in the MIAMI trial. Hypotension and bradycardia not necessarily associated with withdrawal of drug were more common in the metoprolol group (p <0.001). Atrioventricular block I was more common in the metoprolol group (p <0.03), whereas no such difference was observed for atrioventricular block II and III, asystole or pacemaker implantations. Left ventricular failure was observed no more often in the metoprolol group. The occurrence of cardiogenic shock also did not differ between the groups. Cardiac glycosides were used more in the placebo group, but diuretic and furosemide usage did not differ. For all patients mean furosemide doses and number of diuretic injections were similar in both treatment groups. Atropine (4.1 vs 6.4%) and sympathomimetic (3.2 vs 4.6%) agents were used more often in the metoprolol group during days 0 to 5 (p <0.05). The trial medication was withdrawn temporarily more often in the metoprolol than in the placebo group (p <0.001). However, permanent withdrawal of trial medication occurred with a similar frequency overall in both groups. More patients were withdrawn from the study because of cardiovascular reasons in the metoprolol group (9%) than in the placebo group (5%, p <0.001). Need for open treatment with a β blocker was more frequent in the placebo-treated patients (5 vs 2%, p <0.001). A multivariate analysis indicated that tolerance to metoprolol treatment was not further impaired among patients with a high-mortality risk. Early intervention with metoprolol appeared to be well tolerated generally in these patients and no subgroups could be identified in which tolerability was markedly reduced.

(Am J Cardiol 1985;56:39G–46G)

More than 10 major studies focusing on long-term β blockade after myocardial infarction have presented, in addition to mortality and morbidity data, other more general clinical findings together with data on tolerability.[1–10] Much less is known regarding the acute hospital period. The possible adverse effects of early intravenous β blockade must be considered in relation to the preexisting increased risk of severe and life-threatening complications such as heart failure, cardiogenic shock and severe arrhythmias during this early unstable stage of the disease.

In order to elucidate tolerance, safety and compliance several variables were recorded. This article will deal with patient withdrawal, adverse events, dose alterations and patient compliance. The association between permanent trial medication withdrawal and deaths on the one hand and baseline variables, mortality predictors and definite infarction diagnosis on the other will also be assessed.

Address for reprints: Åke Hjalmarson, MD, Department of Medicine I, Sahlgren's Hospital, S-413 45, Göteborg, Sweden.

Patients and Methods

All randomized patients (n = 5,778) were included in the analysis. The clinical findings are presented for days 0 to 15 and days 0 to 5. For clarity some of the definitions of the protocol are presented below.

Hypotension: If the systolic blood pressure was ≤89 mm Hg at any time, it was recorded as hypotension.

Cardiogenic shock: For reasons of international differences of opinion regarding definition, this entity was not formally defined in the protocol. The principal investigators were asked to apply local definitions to their patients. Generally this meant that in addition to hypotension as just defined, the patients had to have oliguria or other signs of impaired peripheral circulation, e.g., pallor, clamminess or cold sweating if cardiogenic shock were to be recorded.

Drug treatment: Treatment with the following drugs was noted: cardiac glycosides,[11] diuretics, antiarrhythmics,[11] nitrates,[12] anticoagulants, atropine, sympathomimetic agents, calcium-channel blockers[12] and other vasodilators. The total dose of furosemide and the number of injections with diuretics were also recorded. Further, the number of narcotic analgesic injections was noted.[12]

Trial medication withdrawal: Predetermined guidelines for withdrawal of trial medication were presented in

TABLE I Heart Rate (HR), Systolic Blood Pressure (SBP) and Rate-Pressure Product (RPP) Before and After Injection of Placebo or Metoprolol

	Placebo (n = 2,901) Mean	SD	Metoprolol (n = 2,877) Mean	SD
Before injection				
HR	83	14	83	14
SBP	141	23	142	23
RPP × 10^{-2}	118	3	117	3
After injection				
HR	81	14	68	12
SBP	137	23	128	24
RPP × 10^{-2}	111	3	87	2

SD = standard deviation.

Table II in a previous article in this issue.[13] The trial medication could be withdrawn in 3 different ways: temporarily only, temporarily followed by permanent withdrawal and permanently only. If the treatment was temporarily withdrawn, it could be reinstituted gradually 2 days later. If the medication had to be withdrawn a second time it was then permanently withdrawn. More than 1 reason for withdrawal could be reported and thus the data were analyzed in 2 ways. The reasons for withdrawal of medication were analyzed separately. If more than 1 reason was recorded for a patient they were grouped in this consecutive order (1) cardiovascular reasons for withdrawal of trial medication, (2) need for β blockade or other reasons for treatment failure, (3) mistake, (4) unwillingness, (5) noncardiovascular adverse events and (6) others. If treatment was both temporarily and later permanently withdrawn, then only the reasons for permanent withdrawal were recorded. The time of permanent withdrawal was also recorded.

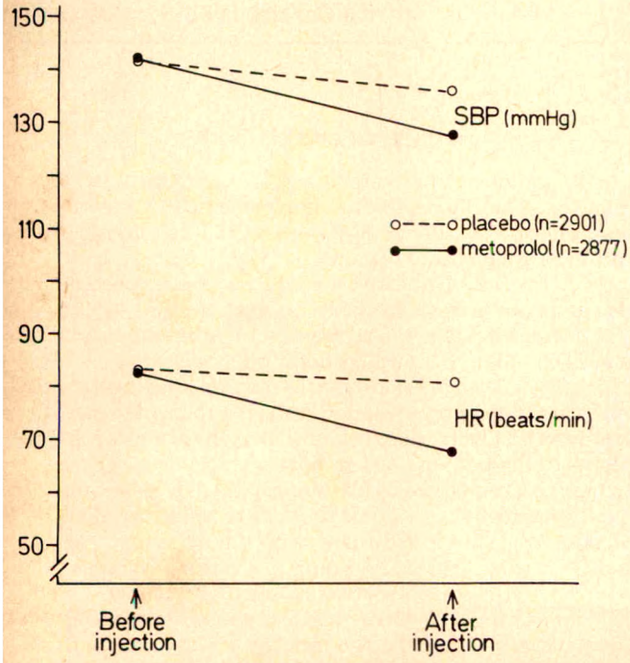

FIGURE 1. Reduction of heart rate (HR) and systolic blood pressure (SBP) in the placebo and metoprolol groups before injection and after 15 minutes.

Other adverse events: Apart from hypotension, bradycardia, heart failure and atrioventricular block, which were recorded elsewhere, other adverse events possibly related to the trial medication were recorded based on observation by the clinical staff or spontaneous reporting by the patient. The events were classified according to Adverse Reaction Terminology of the World Health Organization.[14]

Compliance: Compliance to trial treatment was judged by tablet counts. The number of returned tablets was recorded as was the number of days on which patients were given full dose, half dose, quarter dose and no dose. Compliance was estimated by expressing as a percentage the number of tablets not returned by the number that should have been taken based on the daily dosage recorded.

Hospital stay: The duration of the hospital period in each patient was calculated as the difference between the recorded dates of discharge and admission.

Emergency code breaking: The treatment code in sealed envelopes for individual patients was provided to all trial centers in the interest of patient safety. These were required to be returned at the end of the study with explanation for opened envelopes.

Statistical methods: The principles of statistical analysis previously described were generally applied.[13]

Results

Mean heart rate, systolic blood pressure and their product did not differ between the placebo and metoprolol groups before injection (Table I). In the placebo group these variables did not differ 15 minutes after injection, but in the metoprolol group they decreased ($p < 0.001$) by 18%, 10% and 27%, respectively (Fig. 1).

Mortality in the metoprolol group was not associated with reduction in heart rate, blood pressure or rate-pressure product.

Clinical observations not necessarily associated with withdrawal of trial medication are presented in Table II. Hypotension and bradycardia were more common in the metoprolol group ($p < 0.001$ and $p < 0.001$, respectively). Atrioventricular block I was more common in the metoprolol group during days 0 to 5 ($p < 0.03$); no such difference was observed for atrioventricular block II and III, asystole or pacemaker implantations. Atrial fibrillation or flutter was observed less often in the metoprolol group. Similarly, other supraventricular tachyarrhythmias were seen only half as frequently in the metoprolol patients as among placebo patients.[11] The occurrence of left ventricular failure or cardiogenic shock did not differ between the groups.

The use of concomitant medication during the whole study period (days 0 to 15) and the early phase (days 0 to 5) is presented in Table III. The data on cardiac glycosides and other antiarrhythmics have been considered in more detail elsewhere in this issue,[11] as have those for treatment of chest pain.[12] In general these agents were used less often in the metoprolol group. Other vasodilators also tended to be less used in the metoprolol group during days 0 to 5 ($p = 0.11$) and days 0 to 15 ($p = 0.09$).

The frequency of diuretic and furosemide usage did not differ between the treatment groups ($p > 0.20$), nor did the average number of diuretic injections or dose

SD = standard deviation.

of furosemide among all patients or among those receiving such treatment (Table IV). Atropine and sympathomimetics were used more often in the metoprolol group ($p < 0.05$) but the absolute frequency was low. The relation between placebo and metoprolol regarding mortality was unassociated with the concomitant use of other drugs (Table III).

There was no difference between the treatment groups in the mean time between randomization and discharge from hospital—10.4 days (standard deviation 6.8) compared with 10.3 days (standard deviation 5.7) in the placebo and metoprolol groups, respectively.

Trial medication withdrawal: The trial medication was withdrawn temporarily more often in the metoprolol than the placebo group ($p < 0.001$). Similar findings were seen in the frequency with which medication was withdrawn first temporarily and then per-

TABLE V Proportion and Number of Patients in Whom Treatment Was Temporarily and Permanently Withdrawn

	Placebo		Metoprolol	
Temporarily only	2.9	83	6.4	185
Temporarily and permanently	0.6	16	1.8	51
Permanently only	13.3	385	13.6	390
All permanently	13.8	401	15.3	441

manently. However, the overall rate of permanent withdrawal of trial medication did not differ between the treatment groups (Table V).

The reasons for withdrawing medication temporarily only or permanently (Tables VI and VII) differed between the placebo- and metoprolol-treated groups. In both cases more patients in the metoprolol group were withdrawn from the study because of cardiovascular reasons, i.e., hypotension, heart failure and bradycardia, than in the placebo group ($p < 0.001$, Tables VI and VII). Need for open treatment with β blockade was more frequent in the placebo-treated group ($p < 0.001$). There was a tendency ($p = 0.062$) for atrioventricular block to be given more often as a reason for permanent withdrawal in the metoprolol group.

The number of patients permanently withdrawn immediately after the intravenous injection and their subsequent mortality are shown in Table VIII. There was little difference between the treatment groups in the number of deaths, despite more patients discontinuing metoprolol treatment. The number of deaths among all permanently withdrawn patients was 47 in the placebo group and 43 in the metoprolol group (Table VII). The number of deaths for separate and grouped reasons for withdrawal is presented in Table VII and indicates that metoprolol treatment was not associated with harm in any subgroup.

The cumulative number of patients permanently withdrawn by time in the placebo and metoprolol groups is presented in Figure 2. The risk of withdrawal of any kind was highest on days 0 to 2. After day 6 there were only small differences between the placebo and metoprolol groups regarding risk of withdrawal because of any reason.

Permanent withdrawal was more frequent among patients with pulmonary rales on entry, history of congestive heart failure or diuretic treatment before entry. These risk factors did not influence the relative withdrawal rate between the 2 treatment groups. When permanent withdrawals for cardiovascular reasons were analyzed according to mortality risk groupings (Table IX), the frequency of withdrawal tended to rise with the placebo group mortality but trial treatment did not appear to influence this association. The independent variables from the logit model applied to mortality[15] were used in an analysis with this method and the dependent variable was a combination of deaths and permanent withdrawals for cardiovascular reasons. This analysis showed that metoprolol was significantly associated with withdrawal for cardiovascular reasons. No other significant interactions were found. Thus there were no indications of impaired tolerance among high-risk patients.

Other adverse events: There were more patients in the metoprolol group with adverse events other than hypotension, bradycardia, congestive heart failure or atrioventricular block ($p = 0.002$) (Table X). The nature of these events is specified in Table XI.

Events commonly associated with β blockade were reported more often in the metoprolol than in the placebo group. In the metoprolol group they tended to be somewhat more pronounced and were more often associated with dose reductions compared with placebo. No serious or life-threatening events were considered to be due to the trial medication.

Dose level, compliance and emergency code breaking: A higher number of patients in the metoprolol group completed the trial after having taken reduced doses (Table XII, $p < 0.001$). The proportion of patients on each trial day who were on full dose, reduced dose, withdrawn or dead is summarized in Figure 3.

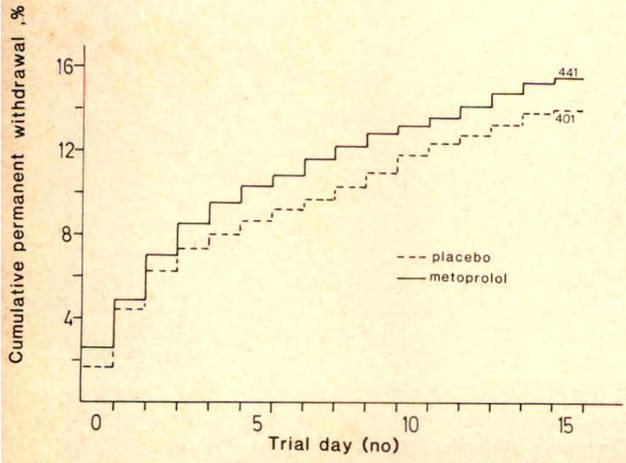

FIGURE 2. Cumulative permanent treatment withdrawals. Cumulative number of patients by trial day.

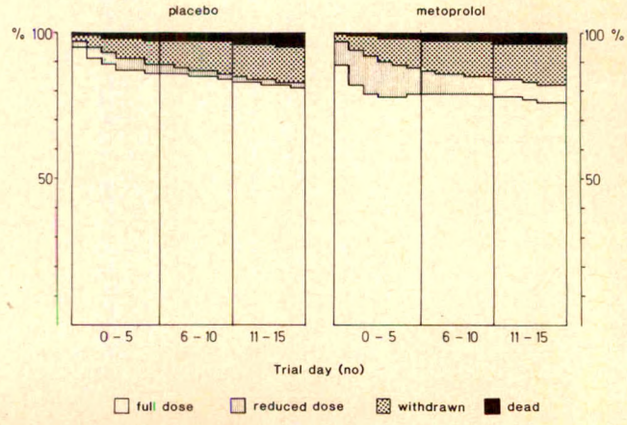

FIGURE 3. Percentage of patients by trial day divided into deaths, temporary and permanent withdrawals and reduced and full doses.

TABLE VI Number of Patients in Whom Treatment Was Temporarily or Permanently Withdrawn in Hierarchic Groups

Hierarchic Group*	Pts. Temporarily Withdrawn		Pts. Permanently Withdrawn			
			No. of withdrawals		No. of deaths	
	Placebo	Metoprolol	Placebo	Metoprolol	Placebo	Metoprolol
Cardiovascular	64	157	142	254	40	37

TABLE IX Proportion and Number of Patients in Whom Treatment Was Permanently Withdrawn for Cardiovascular Reasons by Risk Group* and Number of Deaths in These Patients

	Permanent Withdrawals				Deaths	
	Placebo		Metoprolol		Placebo	Metoprolol
	%	n	%	n	n	n
All patients	4.9	142	8.8	254	40	37
High risk	6.8	70	10.5	106	30	18
Low risk	3.8	72	7.9	148	10	19

* Risk groups are described in Table VI in the article on mortality, pages 15G–22G, this issue.

Information on returned tablets was available for 82% of patients and indicated on average that the placebo group had used 98% of their tablets and the metoprolol group 96%, which was not significantly different.

At the completion of the study, the individually sealed envelopes were returned to the Data Management Center for all randomized patients except 228. The code was broken by the clinical investigators for 128 patients in 36 of the 104 participating centers.

Envelopes were known to be mistakenly opened in 75 cases. Thus the code was broken in the interest of patient safety in 31 placebo-treated and 22 metoprolol-treated patients.

Discussion

It is well established that β blockade introduced both early and late markedly reduces long-term mortality after myocardial infarction. Concern about adverse hemodynamic reactions to β blockade in patients in a very early phase of myocardial infarction has contributed to limiting early administration of β blockers

TABLE XII Percentage of Patients on Full and Reduced Dose of Trial Medication for Different Time Periods

	Placebo (n = 2,901)	Metoprolol (n = 2,877)
Full oral dose	81.2	72.5
Reduced dose		
1–3 days	3.6	4.9
4–6 days	3.7	5.4
7–9 days	2.3	4.0
10–12 days	2.3	3.2
13–15 days	5.5	6.4
16 days	1.4	3.6

to patients with suspected acute myocardial infarction (AMI) in comparison with chronic treatment starting late in survivors of AMI. This apprehension has restricted early intervention mostly to patients with uncomplicated myocardial infarction. Such patients were included in the present study but so were others with mild cardiac decompensation as reflected by pulmonary rales at entry. It should be noted that the protocol of the MIAMI trial excluded patients with a heart rate $\leq$65 beats/min or systolic blood pressure $\leq$105 mm Hg.

The incidence of cardiovascular adverse events, the ensuing numbers of patients in whom treatment was permanently discontinued and the number of deaths among these treatment withdrawals provide accumulating evidence that metoprolol treatment was not harmful. The desired pharmacologic effects of this intervention are also manifested clinically by a higher incidence of bradycardia and hypotension in the metoprolol-treated patients. There was no difference from the placebo-treated patients in the overall occurrence of such undesirable situations as left ventricular failure, cardiogenic shock, asystole and high-degree atrioventricular block. The severity of the observed hypotension, bradycardia, left ventricular failure and atrioventricular block was such that treatment was permanently discontinued more often and atropine and sympathomimetics were administered more frequently in the metoprolol group. Nevertheless, the absolute number of patients who subsequently died among these withdrawals tended to be lower in the metoprolol group.

Although a higher proportion of patients in the metoprolol group deteriorated in association with the intravenous loading dose such that no further treatment was administered, the number and temporal pattern of deaths among these early withdrawals were similar for both treatment groups.

No indication was detected suggesting that withdrawal was associated with an increased mortality that was different in the 2 treatment groups. Mortality was not associated with delay time or hemodynamic response during the injection phase. The multivariate analyses disclosed an association between trial treatment with metoprolol and permanent withdrawal but no other significant interactions. This observation

supports the relevance of the exclusion criteria applied on admission to the trial.

A high proportion of the patients in the 2 treatment groups continued the entire trial period without endpoints or withdrawals on full oral dose. This supports that patient tolerance was good. As previously noted, patient compliance was high as indicated by the tablet counting results.

The pattern of reasons for withdrawal in the 2 treatment groups in this study corresponds with previous experience[5] and was unassociated with delay time. No interaction was detected between the delay time and the effect of metoprolol on incidence of left ventricular failure or of the use of diuretics during the trial period. Therefore, it has not been possible to find evidence that the timing of the institution of metoprolol treatment within the first 24 hours after the onset of symptoms has any influence on the tolerability of this regimen.

Noncardiovascular adverse events were reported more frequently for metoprolol-treated patients but did not result in an increased need to discontinue patients permanently. The spontaneous nature of the adverse event-reporting system and the seriousness of the patients' clinical conditions would tend to dampen the frequency of reporting of these noncardiovascular events. Nevertheless, some known β-blocker adverse reactions have emerged in the metoprolol-treated patients but they did not precipitate a significantly higher rate of withdrawal and were unrelated to mortality. These findings are in agreement with experiences from other large-scale postinfarction studies.[16] In most large, late-entry studies the overall proportion of adverse effects has been quite similar in the placebo and treatment groups.[4,6,8]

The combination of metoprolol and other drug treatment did not appear to worsen patient prognosis for any of the documented concomitant therapies.

Patients with evidence of congestive heart failure at entry as reflected by the presence of pulmonary rales or the use of diuretics before randomization were not adversely affected by metoprolol treatment compared with those patients without signs of heart failure at entry. Thus, mild cardiac decompensation should not be a contraindication to early intervention with metoprolol.

The central hemodynamic effects of metoprolol during the 24 hours after entry have been studied in a subset of patients in the MIAMI trial.[17] Heart rate, systolic blood pressure and cardiac index were all immediately reduced by 10 to 20% in the metoprolol group and the difference compared with placebo was maintained throughout the 24 hours. Pulmonary capillary wedge pressure (PCWP) in the metoprolol group increased only marginally 30 minutes after injection and the increase was seen only in the patient group with initial PCWP below the median of 13 mm Hg. In patients with initial PCWP above the median a continuous decrease was observed. Thus high initial PCWP was not associated with intolerance to metoprolol.

The experience from this and the previous Göteborg Metoprolol Trial concerning the development of congestive heart failure is somewhat different.[18] The previous study indicated that during the first 4 days after start of treatment there was a significant reduction in the requirement for furosemide in the metoprolol-treated patients despite no difference in the frequency of congestive heart failure between the treatment groups. In the present study there was no difference in the incidence of heart failure during the early phase but, in contrast to the previous study, there was no difference in the use of furosemide between the 2 treatment groups. It would seem, however, that the use of furosemide is poorly related to the recorded variable of left ventricular failure in the present study, because 33% of patients received furosemide during days 0 to 5 while only 21% were reported to have congestive heart failure.

The Belfast Metoprolol Trial[19] found no evidence that metoprolol treatment in patients with AMI significantly increased the risk of heart failure. Similarly, studies of early intravenous treatment with atenolol,[20] propranolol[21] and timolol[22] in patients with suspected AMI have detected no association between β-blocker treatment and the development of heart failure or atrioventricular block.

It appears that early intervention with metoprolol has been generally well tolerated in these patients and no subgroups could be identified in which tolerability to metoprolol was markedly reduced.

Hemodynamic Effects of Metoprolol in Acute Myocardial Infarction*

A Randomized, Placebo-Controlled Multicenter Study

PETER H. HELD, MD, HUUB M. A. CORBEIJ, MD, PETER DUNSELMAN, MD, ÅKE HJALMARSON, MD, PhD, DONAL MURRAY, MRCP, and KARL SWEDBERG, MD, PhD, for the Hemodynamic Study Group of the MIAMI Trial

The central hemodynamic effects of metoprolol in acute myocardial infarction have been studied in a multicenter, double-blind, randomized trial. One hundred and ninety patients with acute myocardial infarction not previously on β blockers with heart rate >65 beats/min and blood pressure >105 mm Hg and without clinical signs of serious heart failure were included. After insertion of a pulmonary artery catheter, patients were randomized to metoprolol, 15 mg intravenously, and 50 mg 4 times a day orally (n = 95) or placebo (n = 95) with a mean delay of 7.2 hours. Hemodynamic measurements were made at baseline and repeatedly during 24 hours. Heart rate, systolic blood pressure and cardiac index were all immediately reduced by 10 to 20% in the metoprolol group and the difference compared with placebo was maintained throughout the 24 hours ($p < 0.001$). Pulmonary capillary wedge pressure (PCWP) in the metoprolol group increased from 13.7 ± 6.7 to a peak of 15.5 ± 5.5 mm Hg 30 minutes after injection. The difference compared with placebo was maintained for 8 hours ($p < 0.01$). This increase was seen only in the patient group with initial PCWP below the median of 13 mm Hg. In patients with initial PCWP above the median a continuous decrease was observed in both the placebo and metoprolol groups. Thus high initial PCWP was not associated with intolerance to metoprolol. Based on hemodynamic measurements tolerance to metoprolol was good.

(Am J Cardiol 1985;56:47G–54G)

Previous reports concerning the hemodynamic effects of acute β blockade in patients with acute myocardial infarction (AMI) have been based on small numbers of patients given the drugs openly and without control groups.[1–9] In the early phase of AMI it is difficult to predict from a clinical examination the corresponding central hemodynamics.[10,11] Further, there might be a time lag between hemodynamic changes and clinical findings.[12] The central hemodynamic response to β blockade in this setting is, therefore, incompletely understood.

The metoprolol in acute myocardial infarction (MIAMI) trial[13] was a large, randomized, double-blind, placebo-controlled, multicenter study. The primary objective of the trial was to study the effect of metoprolol on 15-day mortality. It also provided a unique opportunity to investigate the early hemodynamic response to metoprolol.

The purpose of the present study was to analyze the central hemodynamic changes during the first 24 hours after intravenous and oral administration of metoprolol in patients with a definite myocardial infarction.

Methods and Patients

Patients with suspected myocardial infarction admitted to participating coronary care units were eligible for the

study. Fourteen of the 104 MIAMI centers participated in this optional study (Table I).

The inclusion criteria were: (1) age <75 years, (2) onset of chest pain within 12 hours of catheterization; patients admitted between 12 and 24 hours from onset of symptoms were eligible if heart rate was >90 beats/min, if pulmonary rales were present <10 cm above the lower border or if there was persistent or recurrent chest pain and (3) electrocardiographic signs of AMI with ST elevation or new Q waves.

The exclusion criteria were as follows: (1) current treatment with β-adrenergic blockers or calcium-channel blockers, (2) heart rate ≤65 beats/min, (3) systolic blood pressure ≤105 mm Hg, (4) clinical signs of left ventricular failure, as defined by basal pulmonary rales on auscultation >10 cm, (5) P-Q interval >0.24 seconds or higher degree of atrioventricular block, (6) severe chronic obstructive pulmonary disease or other serious disease with impact on short-term prognosis, (7) implanted pacemaker or (8) resuscitation outside hospital.

Of the 5,778 patients enrolled in the MIAMI trial, hemodynamic data from 201 were received at the Data Management Center. However, data from 11 of these patients were excluded from further analysis because of violations of the entry criteria. Of these, 9 patients did not have electrocardiographic signs of AMI at randomization and did not develop AMI. One patient was withdrawn before blind drug injection and another patient did not receive the blind drug until after 4 hours.

The remaining 190 patients fulfilled the protocol criteria and were randomized according to the MIAMI protocol. There was no separate stratified randomization of these patients; however, the goal was at least 150 patients and this number was considered likely to give a balanced randomization. Informed consent was obtained. Protocol was approved by the Ethical Committee at each participating center.

Clinical management and study variables: All patients underwent right-sided heart catheterization at bedside with a triple lumen balloon-tipped thermistor catheter.[14] Pressures were recorded by means of strain gauge transducers. The reference level was 5 cm below the sternum in the supine position. Cardiac output was determined with the thermodilution method; each recorded value was based on a mean of at least 2 accepted measurements within 10%. All measurements and pressure curves were recorded on paper and saved for later analyses.

An arterial catheter was positioned in the radial, brachial or femoral artery (East Birmingham Hospital used cuff readings only). After insertion of the catheters the patients rested 10 minutes; then a control reading including cardiac output, arterial pressures, heart rate, mean right atrial pressure, pulmonary artery pressure and mean pulmonary capillary wedge pressure (PCWP) was performed. The study drug (metoprolol, 15 mg, or placebo) was then administered intravenously in 3 divided doses with 2-minute intervals, according to the MIAMI protocol. Oral drug (metoprolol, 50 mg, or placebo) was given immediately after the 10-minute and 6-, 12- and 18-hour readings. If necessary, dose adjustments were made according to the MIAMI protocol. Hemodynamic measurements were repeated at 10 and 30 minutes, as well as after 1, 2, 4, 6, 8, 12, 18 and 24 hours.

The following indexes were derived from the measurements obtained. Left ventricular stroke work index equalled (mean systolic arterial pressure − PCWP) × stroke volume index × 0.0136. Systemic vascular resistance equalled 80 (mean arterial pressure − right atrial pressure)/cardiac output. Rate-pressure product equalled systolic arterial pressure × heart rate.

Medication other than the trial drug was avoided shortly before and within 30 minutes after the control readings. Administration of such drugs was intended to be based purely on bedside clinical evaluation of the patient, in a fashion identical to that of all other MIAMI patients.

Statistical analysis: At baseline a comparison of background variables was made both between the placebo and the metoprolol group, and between the hemodynamically studied patients and all MIAMI patients admitted within 12 hours with electrocardiographic signs of AMI. Chi-square tests were used for these comparisons.

* = $p < 0.05$; ** = $p < 0.01$; *** = $p < 0.001$ (hemodynamic group vs MIAMI patients). Differences between the placebo and the metoprolol groups were not significant.

Hemodynamic variables were compared at baseline and during 24 hours. At baseline this was done by means of a Student *t* test. Thereafter the variables were compared by application of the "area-under-the-curve" method. For each patient the area was calculated using the trapezoidal rule. The period 0 to 24 hours was divided into 3 intervals: 0 to 1, 1 to 8 and 8 to 24 hours. For each interval the individual area under the curve was calculated. The differences between the distributions of the areas under the curve for the whole trial period and for each interval were then tested between the placebo and metoprolol groups using a *t* test.

A p value of <0.05 was considered significant. In the text and tables, mean values ± standard deviation are presented. In figures the mean ± standard error of the mean is shown.

Data management: The same procedures as for the main MIAMI trial were used in this optional study. A 1-page report form was used and data were edited, checked and entered into the computer at the Data Management Center.[13]

Results

One hundred and ninety patients were included in the analysis. All fulfilled the criteria for a definite infarction. There were 95 patients allocated to placebo and metoprolol, respectively. At randomization, background variables were not significantly different between the 2 treatment groups (Table II). The patients in the hemodynamic protocol were also compared with all MIAMI patients who had electrocardiographic signs of AMI at entry and were randomized within 12 hours after onset of symptoms (n = 2,860). The catheterized patients compared with the other MIAMI patients had a longer delay time from onset of symptoms (7.2 ± 3.8 vs 5.6 ± 2.8 hours, $p < 0.001$). Twenty patients (11%) were randomized between 12 and 24 hours from onset of symptoms. There were fewer patients with previous myocardial infarction (5 vs 13%, $p < 0.01$) and basal pulmonary rales were twice as common (32 vs 16%, $p < 0.001$) among the catheterized patients.

Trial drug administration: Full intravenous loading dose of trial drug (15 ml) was given to all placebo patients and to 86 (91%) patients in the metoprolol group. Six of the 9 patients with reduced intravenous dose later received oral blind drug according to the MIAMI protocol. All 9 were included in the metoprolol group in the analysis.

There were 7 placebo and 8 metoprolol patients who did not receive 1 or more oral dose. This was due to hypotension in 12 patients (6 placebo, 6 metoprolol), heart failure in 2 patients (1 placebo, 1 metoprolol) and bradycardia in 1 metoprolol-treated patient.

Concomitant therapy: After randomization a total of 41 placebo- and 40 metoprolol-treated patients received some medication (including analgesics) in addi-

tion to the trial drug. Diuretics (18 placebo, 22 metoprolol), sympathomimetics (3 placebo, 1 metoprolol) and vasodilators (7 placebo, 7 metoprolol) were equally distributed between the 2 groups.

During the first hour after randomization 6 placebo and 4 metoprolol patients received diuretics or nitroprusside or sympathomimetics.

Hemodynamic response: In Table III the overall hemodynamic findings are presented. The baseline recordings did not show any significant difference between the treatment groups in any of the variables.

Heart rate (Fig. 1) in the metoprolol group decreased from 84 ± 14 to 68 ± 13 beats/min after 10 minutes. In all the following readings heart rate continued to be significantly lower by 10 to 15% in the metoprolol compared with the placebo group ($p < 0.001$).

Systolic arterial blood pressure (Fig. 1) decreased in the metoprolol group from 145 ± 28 to 128 ± 29 mm Hg after 10 minutes. The systolic pressure continued to be lower by 5 to 10% during the observation period ($p < 0.01$). However, the diastolic pressure (Fig. 1) was not significantly lower than in the placebo group. The mean arterial pressure (Fig. 1) was reduced after 10 minutes and thereafter ($p < 0.01$).

Cardiac index (Fig. 1) was immediately reduced from 2.9 ± 0.7 to 2.2 ± 0.6 liters/min · m^2 in the metoprolol group. Thereafter a gradual increase to 2.5 ± 0.6 liters/min · m^2 after 4 hours was seen, but the difference between the treatment groups remained during the entire study period ($p < 0.001$). Reduction of cardiac index in the metoprolol patients was the same percentage in patients with an initial reading above or below the median (2.9 liters/min/m^2) −28% and 21%, respectively.

In the metoprolol group stroke volume index was reduced within the first 8 hours (Fig. 1). It fell from 36 ± 10 to 32 ± 9 ml/beat/m^2 ($p < 0.001$) after 1 hour. Thereafter a gradual increase was observed and after 8 hours no difference was observed.

The pulmonary capillary wedge pressure (PCWP) (Fig. 2) in the metoprolol group increased slightly from 13.7 ± 6.7 to a maximum of 15.3 ± 5.4 mm Hg after 30 minutes. The difference compared with the placebo group was maintained for 8 hours ($p < 0.01$). Thereafter there was no significant difference between the groups.

In the metoprolol-treated patients with an initial PCWP below the median (13 mm Hg) the pressure increased from 8.7 ± 3.5 to 12.4 ± 3.9 mm Hg after 1 hour (Fig. 3). As a result PCWP was significantly higher among metoprolol-than placebo-treated patients, with an initial reading below the median for the first 8 hours ($p < 0.05$). Above the median, the PCWP fell in the metoprolol groups from 19.4 ± 4.6 to 17.6 ± 5.7 mm Hg and in the placebo group from 18.5 ± 4.2 to 15.3 ± 5.5 mm Hg after 1 hour. For the whole observation period therefore, there was no significant difference compared with the placebo group. This dependency on initial PCWP is shown in Figure 4. It also shows the

situation for individual patients at the time for maximal change.

The patients in the upper PCWP quartile (>18 mm Hg, n = 42) were compared in the same way. The metoprolol group (n = 25) decreased from 22.1 ± 4.2 to 13.5 ± 3.6 mm Hg at 24 hours, which was not significantly different from the placebo group. Similarly, the 14 metoprolol and 11 placebo patients in the upper quartile who did not receive any medication except for the trial drug showed a pronounced decrease in PCWP. In metoprolol patients it decreased from 22.6 ± 5.1 to 13.9 ± 3.6 mm Hg and in placebo patients from 23.1 ± 3.9 to 13.6 ± 5.5 mm Hg at 24 hours.

In the metoprolol group the pulmonary artery pressures were slightly higher than in the placebo group during the observation period, but no clear differences were seen (Fig. 2). Right atrial pressure (Fig. 2) in the metoprolol group increased from 5.6 ± 4.4 to a maximum of 7.8 ± 4.4 mm Hg at 30 minutes. The difference to the placebo group was significant during 24 hours ($p < 0.01$).

Rate-pressure product (Fig. 5) fell immediately in the metoprolol group after injection and was considerably reduced throughout the study period ($p < 0.01$).

The systemic vascular resistance (Fig. 5) increased in the metoprolol group from 1,490 ± 490 to 1,730 ± 520 dynes s cm^{-5} after 10 minutes. This initial increase compared with the placebo group was maintained during the first 8 hours ($p < 0.01$); then a gradual attenuation of the difference was seen and after 8 hours no significant difference remained.

Left ventricular stroke work index (Fig. 5) was reduced from 54 ± 18 to 44 ± 16 g · m/m^2 after 10 minutes. This reduction compared with the placebo group was then maintained during the trial period ($p < 0.01$).

The metoprolol response was not associated with age, sex or delay time between onset of symptoms and randomization.

In a subgroup (n = 27, 10 placebo and 17 metoprolol patients) with initial heart rate above the median (80 beats/min), PCWP above the median (13 mm Hg) and cardiac index below the median (2.9 liters/min · m^2), the hemodynamic response to metoprolol was similar to that described for each variable. Of these patients 3 of 10 in the placebo and 2 of 17 in the metoprolol group died during the 15-day MIAMI trial period.

Of the 190 patients studied there were 9 deaths (4.7%) during the 15-day follow-up, 5 in the placebo and 4 in the metoprolol group.

Discussion

This study is the first large placebo-controlled evaluation of central hemodynamic effects of β blockade in AMI. The studied patients were representative of the MIAMI population with electrocardiographic signs of infarction at admission with the exception of pulmonary rales, which were more common in the first group. It is unclear if this is due to a selection of patients with higher left ventricular filling pressures or a more detailed evaluation of those patients considered for catheterization. A minor part of the difference is explained by the fact that rales were an inclusion criterion after 12 hours delay. The other differences compared with the main MIAMI population with electrocardiographic changes are the lower incidence of previous infarction and the longer delay time due to the catheterization procedure.

A number of uncontrolled studies of central hemodynamic effects of β blockade have been published.[1–9] Propranolol was studied in 7,[1–7] metoprolol[8] and practolol[9] in 1 study each. A comparison of those and the present results is difficult due to differences in patient selection and delay times. Most of these earlier data were obtained at 1 single measurement shortly after administration of the drug. In the present trial the initial reaction to metoprolol was studied as well as the hemodynamic changes during 24 hours.

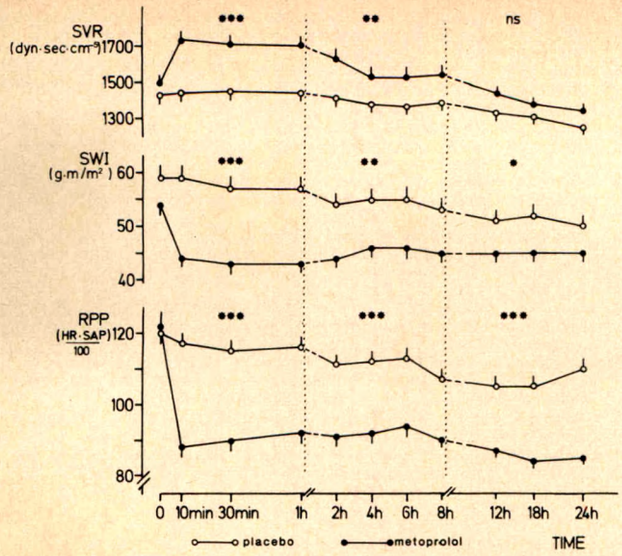

FIGURE 5. Hemodynamic profiles during the 24 hour study period. Time axis and p values as in Figure 1. SVR = systemic vascular resistance; SWI = stroke work index; RPP = rate-pressure product.

Systolic blood pressure, heart rate and thus rate-pressure product were reduced. Together with the reduction in stroke work index, this suggests a decreased myocardial oxygen consumption.[15,16] However, the diastolic arterial pressure did not fall, suggesting an unchanged myocardial diastolic perfusion pressure.

The increase in PCWP observed in the metoprolol group was small but significant compared with placebo for 8 hours. This observation of a slight increase in PCWP is in agreement with Cairns et al.[7] However, Mueller et al[4] did not find any change in PCWP in their pooled population of 55 patients treated with propranolol. The increase in PCWP in our patients was only observed in the group of patients with an initial PCWP below median.

The patients with elevated baseline PCWP are of particular interest. This patient population constitutes a high-risk group[10,11,17] with increased mortality. It is in this group that the negative inotropic effect of metoprolol is most worrisome.

However, we found a continuous decrease of PCWP in these patients. The largest decrease in PCWP was observed in the upper quartile (PCWP >18 mm Hg). There was no difference between the placebo and metoprolol groups. This decrease was found both in patients given diuretics or other drugs and in those who had no medication during the observation period. A similar observation regarding high filling pressures has been reported by Mueller et al[3] for 6 patients with initial PCWP >15 mm Hg treated with propranolol. Málek et al[8] reported a normalization of increased filling pressures in a small patient population with the same dose of metoprolol as in this study.

The decrease in PCWP among these potentially high-risk patients was similar in the placebo and metoprolol groups. It may be that in this group the negative inotropic effects of metoprolol are balanced by a more pronounced antiischemic effect on the severely hypoxic myocardium.

An alternative explanation could be "regression to the mean." However, this could not explain the different response between the placebo and metoprolol groups below and above the median PCWP.

The decrease in patients with high baseline PCWP might indicate improvement of the diastolic myocardial function owing to increased myocardial distensibility. There are several studies suggesting that the elevated PCWP in the ischemic myocardium is in fact due to increased myocardial stiffness.[18,19] However, the exact mechanism is debated.[20]

The reduction in cardiac index in the metoprolol group was mainly due to a reduction of heart rate even though a reduction of stroke volume was also observed. After 8 hours it was due entirely to the reduced heart rate. The decrease in stroke volume in metoprolol-treated patients was accompanied by an increase in PCWP. This suggests a depressed Starling curve in these patients. The importance of this observation is difficult to evaluate as an increase in filling pressure was observed only in the patient group with initial pressures below median.

The increase in systemic vascular resistance during the first 8 hours might be due to a baroreceptor-mediated direct effect on the α_1 receptors, in response to the fall in arterial blood pressure.[21] However, the circulating catecholamines could have some contributory effect on this change in vascular resistance. The hemodynamic response was not significantly influenced by age, delay time or sex. This has previously not been reported after administration of β blockers.

In summary, we have been able to describe the central hemodynamic reaction to metoprolol in patients with AMI. An acute reduction of systolic blood pressure, cardiac index and heart rate was the most impressive and consistent effect. These effects might all indicate decreased myocardial energy production and thus a reduction of myocardial oxygen consumption. An increase in PCWP was only seen in the group of patients in whom initial filling pressures were low; in contrast, the PCWP in the group with high initial values decreased in both metoprolol- and placebo-treated patients. Thus metoprolol appeared to decrease myocardial oxygen consumption without adversely affecting PCWP. With this patient selection we could not identify any subgroup of patients in which the effects of metoprolol were unfavorable.

Thus, a fall in cardiac index or blood pressure within the limits reported here should not contraindicate continued treatment, nor should high PCWP per se be an argument against metoprolol treatment. Instead, bedside clinical findings, such as systolic blood pressure and lung rales, should be evaluated when the decision to use metoprolol is made.

General Discussion

The MIAMI Trial Research Group

The purpose of this article is to relate the results of the MIAMI trial to the findings from other postinfarction studies with β blockers and to draw general conclusions from this collective experience.

The benefit of long-term β blockade as prophylactic treatment to reduce mortality and morbidity after an acute myocardial infarction (AMI) has been unequivocally established and this therapeutic approach has gained increasing acceptance. The mortality reduction amounts to about 25% after 3 years of follow-up in well-conducted trials.[1,2] These results have been obtained mainly in studies in which the oral treatment has been started at least 5 days after confirmation of the infarction.

The Göteborg Metoprolol Trial[3] represented a step forward in assessing intervention begun within a few hours of onset of symptoms of AMI. Early intravenous treatment followed immediately by an oral regimen was found to be safe, and there was a 36% lower mortality rate in the metoprolol group compared with the placebo group after 90 days, a statistically significant difference. This relative mortality reduction was identical to that observed in the Norwegian Timolol Trial,[2] but in that late-entry study it was not achieved until 2 years after the start of treatment. This implies that more lives can be saved in a shorter period of time if the treatment is started immediately after arrival in a hospital.

There is still some uncertainty regarding whether the benefit:risk ratio during the in-hospital phase warrants the early start of treatment with β blockade in patients with suspected AMI. The MIAMI trial was designed to investigate this question further; the primary objective was to evaluate the effect of early intervention with metoprolol on hospital mortality.[4] Other important indexes of morbidity and tolerability were also evaluated. Based on a subgroup analysis of the Göteborg Metoprolol Trial,[4] the sample size was estimated to be adequate to detect a significant difference between treatments in mortality after 15 days.[5]

The MIAMI trial[6] aimed to select a group of patients with higher sympathetic activity but not already on treatment with β blockers or calcium-channel blockers, and this group was expected to have a placebo mortality of 7% after 15 days. The observed placebo mortality (4.9%) was considerably lower than predicted, and the difference between the treatment groups was 13% in favor of metoprolol—not statistically significant with a 95% confidence limit for the relative effect of metoprolol ranging from an 8% excess to a 33% reduction in mortality.[7]

These findings from the MIAMI trial have been combined with results from other early-entry studies with β blockers.[8] These data on nearly 14,000 patients indicate a difference of 10% in the in-hospital death risk with 95% confidence limits, ranging from an excess mortality of 5% to a 22% reduction in death risk. A recently completed study[9] of early intervention with atenolol in AMI patients found a 13% difference in total mortality after 7 days. When these data were pooled with those above,[8] there was a significant ($p = 0.03$) difference of 11% in the in-hospital death risk. The combined evidence in some 30,000 patients from these early-intervention studies suggests that even in relatively low-risk coronary care unit patients with an in-hospital mortality rate around 5%, early treatment with metoprolol can reduce early mortality.

A retrospectively designed multivariate analysis of the MIAMI mortality data indicated that there was a considerable proportion of patients at a low in-hospital death risk in whom a difference in mortality between treatment groups could not be detected.[7] There was an indication among the remaining patients that metoprolol had an increasing beneficial effect on mortality with increasing death risk.

It seems plausible that the heterogeneity in death risk among the MIAMI patients, with a preponderance of patients having a spontaneously benign course, may be a major reason that the overall difference between the treatments was not more pronounced.

The results of the MIAMI trial show that very early institution of metoprolol treatment can prevent infarct development and limit indexes of infarct size.[10,11] These effects are strongly dependent on delay time; the earlier treatment starts, the better the effect is. Patients with a higher sympathetic tone also seem to benefit more. These findings are in agreement with the observations from metoprolol[12–15] and other β blocker studies[16–19] concerning effects on indexes of infarct size.

From the Göteborg Metoprolol Trial,[20] the lower requirement for furosemide in the metoprolol-treated patients is supportive evidence that metoprolol limited the evolution of myocardial necrosis and reduced the severity of congestive heart failure. Again, that effect was inversely related to delay time. No differ-

ence in the mean dosages of furosemide was detected between the treatment groups in the MIAMI trial, in which many more patients were given furosemide.[21]

The incidence of a recurrent infarction during the study period was lower in the Göteborg Metoprolol Trial[3] (days 4 to 90) and tended to be lower in the MIAMI trial[9] (days 4 to 15). Prophylactic treatment has also been shown to prevent recurrent infarction in late-intervention studies.[1,2,22,23] It seems reasonable to believe that similar pathophysiologic mechanisms are involved in the development of the very first infarction and the reinfarction and that both events are favorably influenced by metoprolol.

Beta blockers are well established in the treatment of patients with angina pectoris to prevent pain and improve work capacity. The Göteborg Metoprolol Trial[12,14,24] showed that early institution of metoprolol in suspected AMI patients reduced ongoing chest pain and elevated ST segment, prevented recurrent chest pain and reduced the need of analgesics during the initial hospital phase. The MIAMI trial[25] supports these findings, showing a lower requirement for narcotic analgesics and other antianginal drugs, and a shorter duration of pain among metoprolol-treated patients.

Several studies have indicated that β blockers can reduce supraventricular as well as ventricular arrhythmias in patients with AMI.[16,26,27] The Göteborg Metoprolol Trial[28] showed a marked reduction of both types of arrhythmias and of the need of antiarrhythmic agents and digitalis during the hospital phase. Metoprolol treatment clearly prevented ventricular fibrillation and ventricular tachycardia.[28] In the MIAMI trial,[29] metoprolol treatment reduced the incidence of supraventricular tachyarrhythmias and the need for digitalis and other antiarrhythmic agents, but did not significantly affect the number of patients who developed ventricular fibrillation or ventricular tachycardia. Again, there were important differences between the 2 studies. In MIAMI there was a higher use of concomitant prophylactic antiarrhythmic medications; these were possibly given to patients at a high risk of developing ventricular fibrillation, because the incidence of ventricular fibrillation in the placebo group was only about half the incidence in the Göteborg Metoprolol Trial.

Favorable effects on early ventricular fibrillation have also been obtained with propranolol.[30] The fact that metoprolol,[23] propranolol[2] and timolol[1] in late-entry studies have shown a marked prophylactic effect against sudden cardiac deaths supports the idea that these β blockers are effective in preventing ventricular fibrillation.

Drug tolerance has been good in the long-term studies.[1,2] In the Göteborg Metoprolol Trial[3] tolerance was also good when metoprolol was injected intravenously early in the course of an AMI when patients were likely to be hemodynamically labile. Anxiety has persisted, however, regarding the safety and tolerability of intravenous β blockade in such patients. The MIAMI trial, based on close to 3,000 patients actively treated, firmly establishes that intravenous administration of metoprolol is safe when standard contraindications are observed.[21,31] It should also be stressed that patients with basal pulmonary rales were involved. The findings from the hemodynamic subgroup[32] of the MIAMI trial show that high left ventricular filling pressure is not further elevated by metoprolol during the 24 hours after the start of treatment. Similarly atrioventricular conduction was not seriously impaired by treatment.

The MIAMI trial patients were selected from the segment of all coronary care unit admissions having heart rate and blood pressure levels in the upper parts of the total distribution and were therefore not representative of all patients. They were not previously treated with β blockers. The actually observed global mortality difference was 13% from a 4.9% placebo mortality level. Thus, the MIAMI trial failed to refute the null hypothesis most probably because of a loss of statistical power. This might be due to the inclusion of a large proportion of patients with a spontaneously benign course and low mortality. This notion is supported by the multivariate analyses showing that as the placebo mortality increases to around 7% in segments of the study sample, the mortality reduction increases to about 30%. The question regarding the possibility of lowering the very early mortality in myocardial infarction by metoprolol treatment is not yet completely resolved. However, the confidence interval around the MIAMI mortality result includes that of the Göteborg Metoprolol Trial.

The final decision regarding choice of treatment in patients with AMI must be based on a global assessment of as many drug effects as possible. Early treatment with metoprolol, starting with an intravenous loading dose, seems to be indicated for a substantial proportion of patients admitted to coronary care units.

Angina Protection with Benefits for a Lifetime

ONCE-DAILY CONTROL WITH HEART-SAVING BENEFITS

By reducing heart rate and cardiac contractility, INDERAL LA helps protect the heart from the potentially serious and debilitating consequences of ischemia. A highly effective antianginal agent for around-the-clock control of symptoms, INDERAL LA also provides cardiovascular protection for a sense of security in the years ahead.

PROTECTION AND EXPERIENCE NO CALCIUM BLOCKER CAN MATCH

Unlike calcium blockers, INDERAL LA—either alone or with a nitrate—is recommended for early treatment of angina in the majority of patients. Equally important, INDERAL LA delivers the proven performance and safety profile of INDERAL tablets—confirmed by millions of patients during 16 years of clinical use.

START WITH 80 MG ONCE DAILY

Dosage may be increased to 160 mg once daily, as needed, to achieve optimal control. INDERAL LA should not be used in congestive heart failure, sinus bradycardia, cardiogenic shock, heart block greater than first degree, and bronchial asthma. Please see next page for further details and brief summary of prescribing information.

ONCE-DAILY **INDERAL® LA**
(PROPRANOLOL HCl) LONG ACTING CAPSULES

The appearance of INDERAL LA capsules is a registered trademark of

Wyeth-Ayerst

JUST ONCE EACH DAY FOR SIMPLIFIED CORE THERAPY IN ANGINA

ONCE-DAILY INDERAL® LA (PROPRANOLOL HCl) LONG ACTING CAPSULES

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*
INDERAL® LA brand of propranolol hydrochloride **(Long Acting Capsules)**
DESCRIPTION. Inderal LA is formulated to provide a sustained release of propranolol hydrochloride. Inderal LA is available as 80 mg, 120 mg, and 160 mg capsules.
CLINICAL PHARMACOLOGY. INDERAL is a nonselective beta-adrenergic receptor blocking agent possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available receptor sites. When access to beta-receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

INDERAL LA Capsules (80, 120, and 160 mg) release propranolol HCl at a controlled and predictable rate. Peak blood levels following dosing with INDERAL LA occur at about 6 hours and the apparent plasma half-life is about 10 hours. When measured at steady state over a 24-hour period the areas under the propranolol plasma concentration-time curve (AUCs) for the capsules are approximately 60% to 65% of the AUCs for a comparable divided daily dose of INDERAL tablets. The lower AUCs for the capsules are due to greater hepatic metabolism of propranolol, resulting from the slower rate of absorption of propranolol. Over a twenty-four (24) hour period, blood levels are fairly constant for about twelve (12) hours then decline exponentially.

INDERAL LA should not be considered a simple mg for mg substitute for conventional propranolol and the blood levels achieved do not match (are lower than) those of two to four times daily dosing with the same dose. When changing to INDERAL LA from conventional propranolol, a possible need for retitration upwards should be considered especially to maintain effectiveness at the end of the dosing interval. In most clinical settings, however, such as hypertension or angina where there is little correlation between plasma levels and clinical effect, INDERAL LA has been therapeutically equivalent to the same mg dose of conventional INDERAL as assessed by 24-hour effects on blood pressure and on 24-hour exercise responses of heart rate, systolic pressure and rate pressure product. INDERAL LA can provide effective beta blockade for a 24-hour period.

The mechanism of the antihypertensive effect of INDERAL has not been established. Among the factors that may be involved in contributing to the antihypertensive action are (1) decreased cardiac output, (2) inhibition of renin release by the kidneys, and (3) diminution of tonic sympathetic nerve outflow from vasomotor centers in the brain. Although total peripheral resistance may increase initially, it readjusts to or below the pretreatment level with chronic use. Effects on plasma volume appear to be minor and somewhat variable. INDERAL has been shown to cause a small increase in serum potassium concentration when used in the treatment of hypertensive patients.

In angina pectoris, propranolol generally reduces the oxygen requirement of the heart at any given level of effort by blocking the catecholamine-induced increases in the heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. Propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure and systolic ejection period. The net physiologic effect of beta-adrenergic blockade is usually advantageous and is manifested during exercise by delayed onset of pain and increased work capacity.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential. The significance of the membrane action in the treatment of arrhythmias is uncertain.

The mechanism of the antimigraine effect of propranolol has not been established. Beta-adrenergic receptors have been demonstrated in the pial vessels of the brain.

Beta receptor blockade can be useful in conditions in which, because of pathologic or functional changes, sympathetic activity is detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, greater than first degree, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

Propranolol is not significantly dialyzable.

INDICATIONS AND USAGE. Hypertension: INDERAL LA is indicated in the management of hypertension; it may be used alone or used in combination with other antihypertensive agents, particularly a thiazide diuretic. INDERAL LA is not indicated in the management of hypertensive emergencies.

Angina Pectoris Due to Coronary Atherosclerosis: INDERAL LA is indicated for the long-term management of patients with angina pectoris.

Migraine: INDERAL LA is indicated for the prophylaxis of common migraine headache. The efficacy of propranolol in the treatment of a migraine attack that has started has not been established and propranolol is not indicated for such use.

Hypertrophic Subaortic Stenosis: INDERAL LA is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL LA also improves exercise performance. The effectiveness of propranolol hydrochloride in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta-receptor stimulation. Clinical improvement may be temporary.

CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL (propranolol HCl), like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS. *General:* Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

DOSAGE AND ADMINISTRATION. INDERAL LA provides propranolol hyorochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL tablets to INDERAL LA capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg for mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary especially to maintain effectiveness at the end of the 24-hour dosing interval.

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 80 mg INDERAL LA once daily, whether used alone or added to a diuretic. The dosage may be increased to 120 mg once daily or higher until adequate blood-pressure control is achieved. The usual maintenance dosage is 120 to 160 mg once daily. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 80 mg INDERAL LA once daily, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg once daily. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

MIGRAINE—*Dosage must be individualized.* The initial oral dose is 80 mg INDERAL LA once daily. The usual effective dose range is 160-240 mg once daily. The dosage may be increased gradually to achieve optimum migraine prophylaxis. If a satisfactory response is not obtained within four to six weeks after reaching the maximum dose, INDERAL LA therapy should be discontinued. It may be advisable to withdraw the drug gradually over a period of several weeks.

HYPERTROPHIC SUBAORTIC STENOSIS—80-160 mg INDERAL LA once daily.

PEDIATRIC DOSAGE—At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

*The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

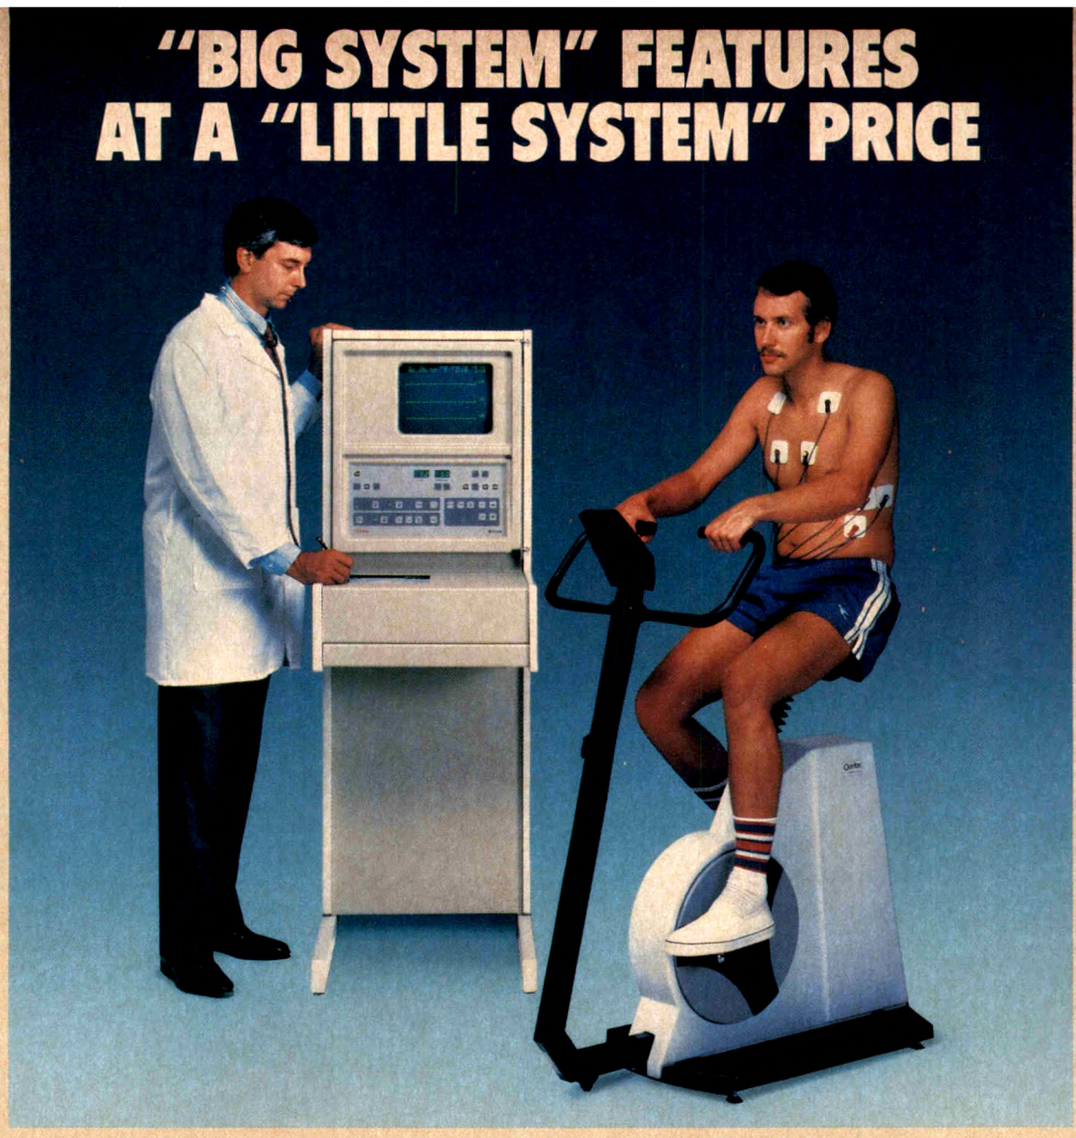
"BIG SYSTEM" FEATURES AT A "LITTLE SYSTEM" PRICE



Quinton Q3000B Stress Test System

An affordable stress test system no longer means settling for second best. Not if your choice is Quinton's new Q3000B System—featuring our Q3000B Monitor and Corival 400 Ergometer.

Now the sophistication you require can be yours without the high price tag. Only Quinton Instrument Company offers you state-of-the-art stress test equipment with advanced features such as *ASVV, signal averaging, and programmability* at a "little system" price. That's not surprising—we were pioneers in the stress testing field, and we have worked very hard to provide only top quality equipment you know you can rely on. That's why we remain the world leader in stress systems.

The Q3000B may be just the system you need, particularly if you have limited work area available or if you are testing patients with physical limitations that preclude using treadmill testing.

- Some people, such as geriatric patients with low cardiopulmonary or muscular reserve, may be unable to walk or run on a treadmill.
- The initial workload can be set low on the bicycle ergometer and can be increased in small, precise increments.
- It is easier to identify and prescribe a precise, very low exercise program for physically impaired patients.
- The bicycle ergometer is often preferred for pediatric cardiology.
- The Q3000B System is less expensive and requires less floor space than an equivalent treadmill-based system.

Discover just how much your dollar can buy. We invite you to learn more about our stress test systems. Then compare and you will know why Quinton stress testing systems are unequalled when it comes to features and value. For more information, please contact:

PRODUCT INFORMATION

NORMODYNE®

brand of labetalol hydrochloride

Tablets

BRIEF SUMMARY

INDICATIONS AND USAGE

NORMODYNE (labetalol HCl) Tablets are indicated in the management of hypertension. NORMODYNE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS

NORMODYNE (labetalol HCl) Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS

Cardiac Failure Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, NORMODYNE (labetalol HCl) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered NORMODYNE (labetalol HCl), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, NORMODYNE (labetalol HCl) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue NORMODYNE (labetalol HCl) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis and emphysema) Patients with bronchospastic disease should, in general, not receive beta-blockers. NORMODYNE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if NORMODYNE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma Labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heart beat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

PRECAUTIONS

General *Impaired Hepatic Function* NORMODYNE (labetalol HCl) Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with NORMODYNE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with NORMODYNE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with NORMODYNE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests

As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions

In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions

The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C

Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the maximum recommended human dose (MRHD), respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects

Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery

Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers

Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when NORMODYNE Tablets are administered to a nursing woman.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects are mild, transient and occur early in the course of treatment. In controlled clinical trials of 3 to 4 months duration, discontinuation of NORMODYNE (labetalol HCl) Tablets due to one or more adverse effects was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8 to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The incidence rates of adverse reactions listed in the following table were derived from multicenter controlled clinical trials, comparing labetalol HCl, placebo, metoprolol and propranolol, over treatment periods of 3 and 4 months. Where the frequency of adverse effects for labetalol HCl and placebo is similar, causal relationship is uncertain. The rates are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (e.g., dizziness 20%, nausea 14%, fatigue 11%), but the overall conclusions are unchanged.

vision abnormality	1	0	0	0
vertigo	2	1	0	0

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, i.e., a group excluding patients with bronchospastic disease, overt congestive heart failure, or other contraindications to beta-blocker therapy.

Clinical trials also included studies utilizing daily doses up to 2400 mg in more severely hypertensive patients. Certain of the side effects increased with increasing dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are clearly or possibly dose related.

Labetalol HCl Daily Dose (mg)	200	300	400	600
Number of Patients	522	181	606	608
Dizziness (%)	2	3	3	3
Fatigue	2	1	4	4
Nausea	<1	0	1	2
Vomiting	0	0	<1	<1
Dyspepsia	1	0	2	1
Paresthesias	2	0	2	2
Nasal Stuffiness	1	1	2	2
Ejaculation Failure	0	2	1	2
Impotence	1	1	1	1
Edema	1	0	1	1

Labetalol HCl Daily Dose (mg)	800	900	1200	1600	2400
Number of Patients	503	117	411	242	175
Dizziness (%)	5	1	9	13	16
Fatigue	5	3	7	6	10
Nausea	4	0	7	11	19
Vomiting	<1	0	1	2	3
Dyspepsia	1	0	2	2	4
Paresthesias	1	1	2	5	5
Nasal Stuffiness	2	2	4	5	6
Ejaculation Failure	3	0	4	3	5
Impotence	2	4	3	4	3
Edema	1	0	1	2	2

In addition, a number of other less common adverse events have been reported in clinical trials or the literature:

Cardiovascular Postural hypotension, including rarely, syncope.

Central and Peripheral Nervous Systems Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient and usually occurred at the beginning of treatment.

Collagen Disorders Systemic lupus erythematosus; positive antinuclear factor (ANF).

Eyes Dry eyes.

Immunological System Antimitochondrial antibodies.

Liver and Biliary System Cholestasis with or without jaundice.

Musculo-Skeletal System Muscle cramps; toxic myopathy.

Respiratory System Bronchospasm.

Skin and Appendages Rashes of various types, such as generalized maculo-papular; lichenoid; urticarial; bullous lichen planus; psoriaform; facial erythema; Peyronie's disease; reversible alopecia.

Urinary System Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects

In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular Intensification of AV block. See **CONTRAINDICATIONS.**

Allergic Fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.

Gastrointestinal Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical laboratory tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE

Overdosage with NORMODYNE (labetalol HCl) Tablets causes excessive hypotension which is posture sensitive, and sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: *Excessive bradycardia* — administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. *Cardiac failure* — administer a digitalis glycoside and a diuretic. *Hypotension* — administer vasopressors, e.g., norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. *Bronchospasm* — administer a $beta_2$-stimulating agent and/or a theophylline preparation.

Gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 gm/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION

DOSAGE MUST BE INDIVIDUALIZED. The recommended initial dose is 100 mg twice daily whether used alone or added to a diuretic regimen. After 2 or 3 days, using standing blood pressure as an indicator, dosage may be titrated in increments of 100 mg bid every 2 or 3 days. The usual maintenance dosage of labetalol HCl is between 200 and 400 mg twice daily.

Since the full antihypertensive effect of labetalol HCl is usually seen within the first one to three hours of the initial dose or dose increment, the assurance of a lack of an exaggerated hypotensive response can be clinically established in the office setting. The antihypertensive effects of continued dosing can be measured at subsequent visits, approximately 12 hours after a dose, to determine whether further titration is necessary.

Patients with severe hypertension may require from 1200 mg to 2400 mg per day, with or without thiazide diuretics. Should side effects (principally nausea or dizziness) occur with these doses administered bid, the same total daily dose administered three times daily may improve tolerability and facilitate further titration. Titration increments should not exceed 200 mg twice daily.

When a diuretic is added, an additive antihypertensive effect can be expected. In some cases this may necessitate a labetalol HCl dosage adjustment. As with most antihypertensive drugs, optimal dosages of NORMODYNE Tablets are usually lower in patients also receiving a diuretic.

When transferring patients from other antihypertensive drugs, NORMODYNE Tablets should be introduced as recommended and the dosage of the existing therapy progressively decreased.

HOW SUPPLIED

NORMODYNE (labetalol HCl) Tablets, 100 mg, light-brown, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 244, and on the other side the number 100 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0244-04), 500 (NDC-0085-0244-05), and box of 100 for unit-dose dispensing (NDC-0085-0244-08).

NORMODYNE (labetalol HCl) Tablets, 200 mg, white, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 752, and on the other side the number 200 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0752-04), 500 (NDC-0085-0752-05), box of 100 for unit-dose dispensing (NDC-0085-0752-08), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0752-03).

NORMODYNE (labetalol HCl) Tablets, 300 mg, blue, round, film-coated tablets engraved on one side with Schering and product identification numbers 438, and on the other side the number 300 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0438-03), 500 (NDC-0085-0438-05), box of 100 for unit-dose dispensing (NDC-0085-0438-06), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0438-02).

NORMODYNE (labetalol HCl) Tablets should be stored between 2° and 30°C (36° and 86°F).

NORMODYNE (labetalol HCl) Tablets in the unit-dose boxes should be protected from excessive moisture.

For complete prescribing information, please consult package insert.

In 1980, ACS innovation provided the first over-the-wire coronary balloon dilatation catheter system.

As PTCA has become a widely practiced interventional technique the need has grown for innovative systems to perform more complex procedures. ACS has those innovative systems for today and tomorrow. Contact your ACS representative and clinical specialist or call (800) 227-9902 for more information.

dura-tabs® SUSTAINED-RELEASE TABLETS 324 mg

Quinaglute®

quinidine gluconate

- Continuous arrhythmia control
- Well tolerated in long-term therapy[1]
- Less GI upset than with quinidine sulfate[2]
- B.I.D.* dosage for uninterrupted protection

Start the oral agent he can live with

*Some patients may require more frequent (t.i.d.) dosing
Please turn page for brief summary of prescribing information.

References: 1. Selzer A: *Heart Lung* 1982;11:20-23.
2. Podrid P: *Patient Care* 1981;15:100-132.

INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock)
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine. 2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered. 3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring. 4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals. 5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity. 7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal. 8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk. *Information for Patients:* As with all solid oral medications, Quinaglute (quinidine gluconate) Dura-Tabs (sustained-release tablets) should be taken with an adequate amount of fluid, preferably in an upright position, to facilitate swallowing.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

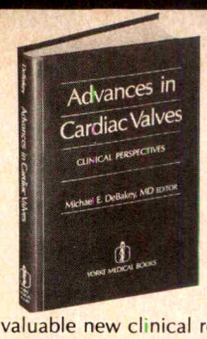
The Most Extensive Compilation of Information on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by
Michael E. DeBakey, MD
0-914316-40-0, 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of the information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

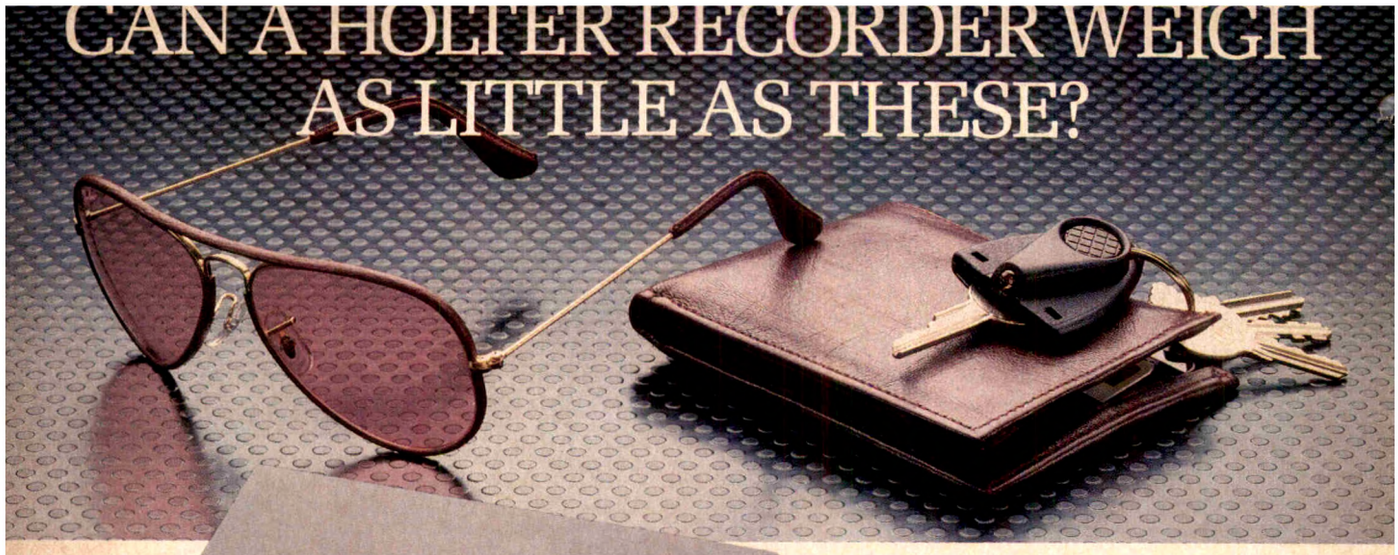
CAN A HOLTER RECORDER WEIGH AS LITTLE AS THESE?



YES...THE NEW "FEATHERWEIGHT" FROM SPACELABS.

INTRODUCING THE SMALLEST, LIGHTEST HOLTER RECORDER AVAILABLE.

The new Spacelabs 90201 Holter recorder weighs just 10 oz., – about the same as some of the everyday items your patients might have in their pockets. And at a tiny 3.2″ × 5.5″ × 0.8″ size, it fits right in a shirt pocket, too.

The latest, most advanced technology has enabled us to put all the reliability, accuracy and capability of our previous generations of Holter recorders – and then some – into this new compact model, for the greatest patient comfort and convenience ever.

It provides 2 channels of ambulatory ECG data, plus a discrete timing track for 24 or 48 hours' continuous recording time. Automatic calibration and a backup internal battery for the LCD clock guarantee accurate event-time correlation. And the patient event marker is easily accessible.

NEW
"FEATHERWEIGHT" 90201 HOLTER RECORDER

Ask your representative for the name of a scanning service in your area.

AND SPACELABS' MOST ADVANCED, ACCURATE, EASY-TO-USE HOLTER ANALYSIS SYSTEM.

Our new 90101 scanner minimizes the inaccuracies inherent in other arrhythmia discriminators via its powerful simultaneous 2-channel discriminator, for more meaningful information. And you can get this information faster and easier than ever before – a full report, including numeric summary, graphic summary and sample beat classification, in just 10-15 minutes – without any operator interaction! Or you can have a fully edited report, using its morphology merge/delete feature, in just 5 minutes. What's more, you can easily program the system to individualize reports to meet your specific needs. It includes an industry standard communications bus – a pathway to the future with the product you purchase today. *And its cost is justified in only 3 scans/month!*

NEW
90101 HOLTER ANALYSIS SYSTEM

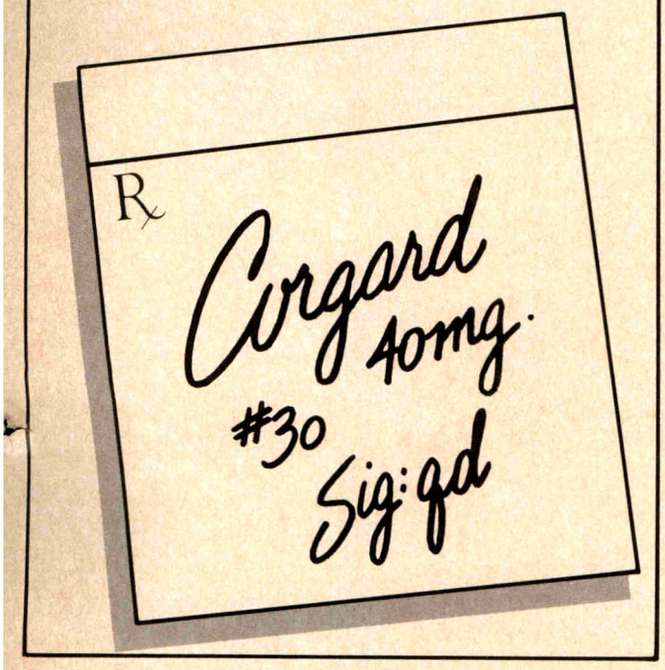
CORGARD®
(nadolol tablets)
R_x for Angina



CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery—Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia—Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis—Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Renal Function—Use nadolol with caution (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients—Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign of impending failure. Advise patients in event of missed doses.

Drug Interactions—Concurrent administration may result in interactions with: Anesthetics, general—exaggeration of the hypotension induced by general anesthetics (see WARNINGS, Major Surgery). Antidiabetic drugs (oral agents and insulin)—hypoglycemia or hyperglycemia; adjust antidiabetic drug dosage accordingly (see WARNINGS, Diabetes and Hypoglycemia). Catecholamine-depleting drugs (e.g., reserpine)—additive effect; monitor closely for hypotension and/or excessive bradycardia.

Carcinogenesis, Mutagenesis, Impairment of Fertility—In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy—In animal reproduction studies with nadolol, evidence of embryo-and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus. Neonates of mothers who received nadolol at parturition have exhibited bradycardia, hypoglycemia and associated symptoms.

Nursing Mothers—Nadolol is excreted in human milk. Exercise caution when nadolol is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular—Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System**—Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory**—Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal**—Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous**—Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision; infrequent reversible alopecia. The following adverse reactions have been reported in patients taking nadolol and/or other beta-adrenergic blocking agents, but no causal relationship to nadolol has been established. **Central Nervous System**—reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal**—mesenteric arterial thrombosis; ischemic colitis; elevated liver enzymes. **Hematologic**—agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic**—fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous**—pemphigoid rash; hypertensive reaction in patients with pheochromocytoma; sleep disturbances; Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia—Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure—Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension—Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm—Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; may be gradually increased in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 40 or 80 mg q.d. (doses up to 160 or 240 mg daily may be needed). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 40 or 80 mg q.d. (doses up to 240 or 320 mg daily may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets.

WHEN YOUR PATIENT IS TRAPPED BY ANGINA AND THE FEAR OF THE NEXT ATTACK

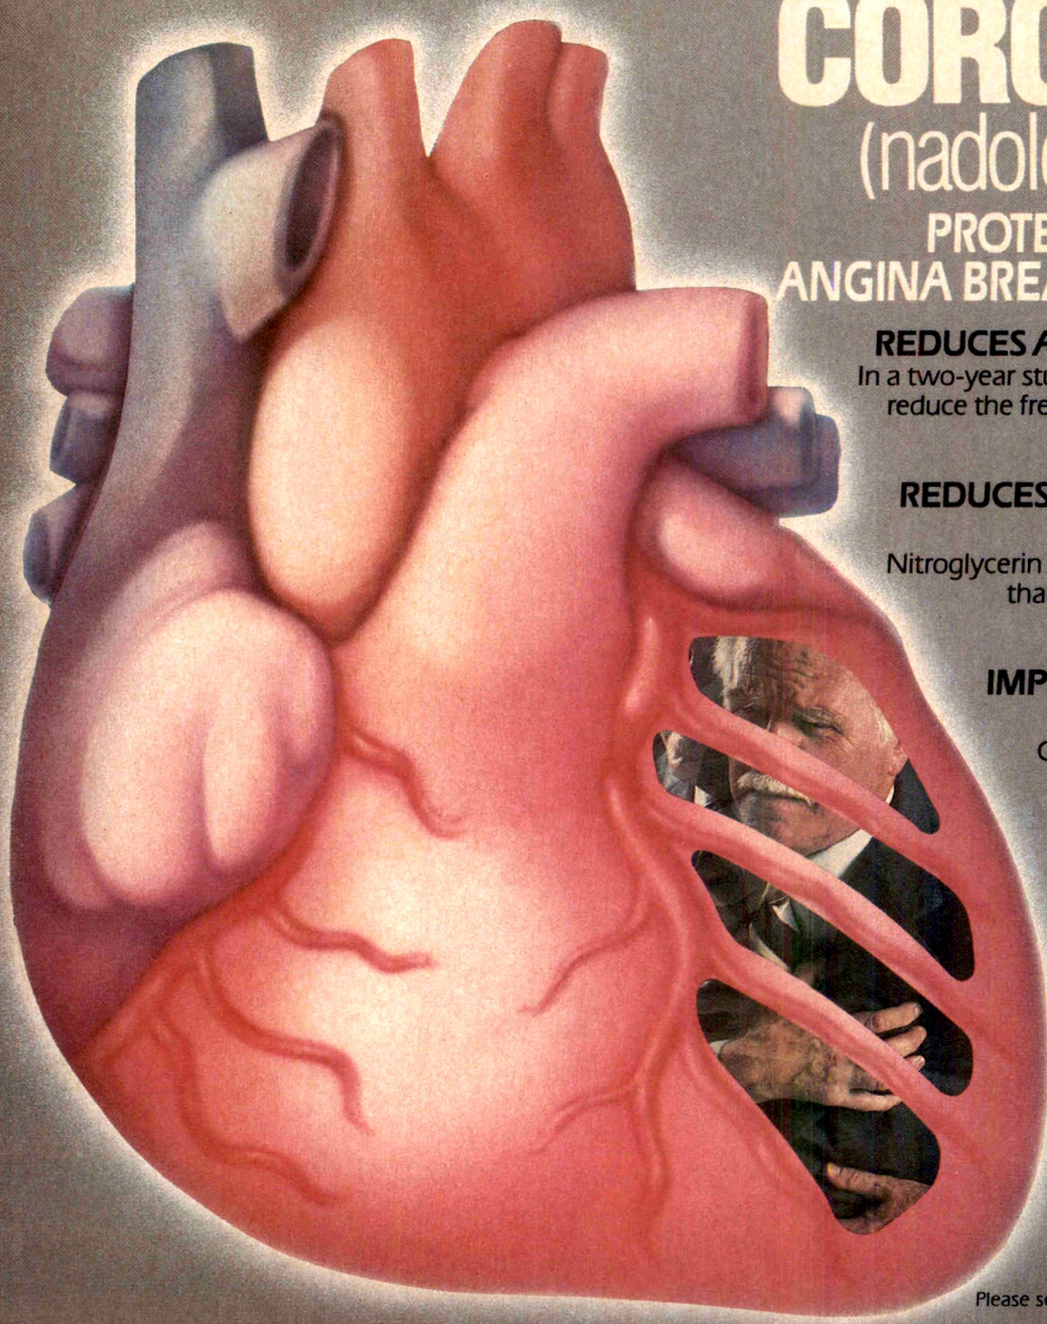
CORGARD®
(nadolol tablets)

PROTECTS AGAINST ANGINA BREAKTHROUGH*

REDUCES ANGINA ATTACKS
In a two-year study, CORGARD helped reduce the frequency of attacks from 5.3 per week to 2.1.[1]

REDUCES NITROGLYCERIN NEED
Nitroglycerin requirements were less than half by the end of the two-year study.[1]

IMPROVES EXERCISE TOLERANCE
CORGARD significantly increases the patient's ability to participate in physical activity.[2]



*The syndrome of recurring symptoms compounded by the fear of impending attacks.

Please see brief summary of prescribing information on adjacent page.

SYSTEMIC HYPERTENSION

913 **Systolic Hypertension in the Elderly Program (SHEP): Antihypertensive Efficacy of Chlorthalidone**

STEPHEN B. HULLEY, CURT D. FURBERG, BARRY GURLAND, ROBERT McDONALD, MITCHELL PERRY, HAROLD W. SCHNAPER, JAMES A. SCHOENBERGER, W. McFATE SMITH, and THOMAS M. VOGT, *for the* SHEP RESEARCH GROUP

Men and women who had isolated systolic hypertension and were at least 60 years old were treated for 1 year with chlorthalidone (25 to 50 mg/day) or matching placebo as the step I drug. Most patients reached goal blood pressure (BP) without requiring a step II drug. The BP response was similar in all age, sex and race subgroups, with an overall difference between the randomized groups of 17 mm Hg for systolic BP ($p < 0.001$) and 6 mm Hg for diastolic BP ($p < 0.001$). The only common adverse effects were asymptomatic changes in the serum levels of potassium (0.5 mEq/liter lower in the chlorthalidone group, $p < 0.001$), uric acid (0.9 mg/dl higher, $p < 0.001$) and creatinine (0.08 mg/dl higher, $p = 0.02$). Compliance was good; more than 80% of the participants were still taking study medications at the end of the year.

921 **Doppler Evaluation of Left Ventricular Diastolic Filling in Children with Systemic Hypertension**

A. REBECCA SNIDER, SAMUEL S. GIDDING, ALBERT P. ROCCHINI, AMNON ROSENTHAL, MACDONALD DICK II, DENNIS C. CROWLEY, and JANE PETERS

To assess left ventricular (LV) diastolic function in systemic hypertension, 11 children with systemic hypertension and 7 normal children underwent M-mode echocardiography and Doppler ultrasound examination of LV inflow. Echocardiographic diastolic relaxation times and filling rates and Doppler diastolic time intervals did not distinguish normal subjects from patients with hypertension. Analysis of the mitral valve Doppler recordings of the patients with hypertension showed an increased peak velocity during atrial contraction (A wave), an increased area under the A wave, a decreased percent of the total area of the mitral valve Doppler waveform in the first one-third of diastole, and an increased percent of the total area of mitral valve Doppler waveform under the A wave compared with that in normal subjects. These findings suggest a relative shift in LV filling toward the latter part of diastole in children with mild systemic hypertension probably caused by altered diastolic compliance.

927 **Systemic Hypertension After Cardiac Transplantation: Effect of Cyclosporine on the Renin-Angiotensin-Aldosterone System**

MARC BELLET, CHRISTIAN CABROL, PAOLO SASSANO, PHILIPPE LÉGER, PIERRE CORVOL, and JOËL MÉNARD

Fifteen hypertensive cardiac transplantation patients (13 of whom were normotensive before transplantation) were treated with cyclosporine. No resulting abnormalities were observed in plasma renin, angiotensinogen or converting enzyme activity, and the level of plasma aldosterone was normal. However, 2 abnormalities

Clinical Clues to MIXED ANGINA *No. 5*

The stairs seem steeper today

Most days she can climb the stairs with no difficulty. But today she was less than half-way up when an angina attack stopped her.

That's the unpredictability of MIXED ANGINA—vasoconstriction coexisting with fixed coronary lesion, to produce a critical reduction of myocardial blood flow.

And because vasoconstriction is an unpredictable event, ischemia and pain occur unpredictably:

- at varying levels of exercise
- at rest, or even during sleep
- upon exposure to cold
- under emotional stress
- diurnally, typically in the morning

PROCARDIA® (nifedipine) is a primary therapy for the patient with MIXED ANGINA. It prevents vasoconstriction in both large coronary arteries and coronary arterioles to maintain myocardial blood flow and oxygen supply. At the same time, PROCARDIA dilates peripheral arteries to reduce afterload and myocardial oxygen demand.

As a result, PROCARDIA can significantly reduce your patient's angina attack rate and need for nitroglycerin.[1]

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Primary Protection in
MIXED ANGINA

Please see PROCARDIA® (nifedipine) brief summary on next page.

The stairs seem steeper today

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PRIMARY PROTECTION IN MIXED ANGINA

Usual Effective Dosage: 30 to 60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases.

A Favorable Safety Profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

Reference:

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 106:644-652, 1983.

Brief Summary
PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA (nifedipine) therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some PROCARDIA patients. No clinical significance for these findings has been demonstrated.

Although PROCARDIA has been used safely in patients with renal dysfunction and has been reported to exert a beneficial effect in certain cases, rare, reversible elevations in BUN and serum creatinine have been reported in patients with pre-existing chronic renal insufficiency. The relationship to PROCARDIA therapy is uncertain in most cases but probable in some.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80%) and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg per day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is initiated in a patient currently receiving cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryotoxic in rats, mice and rabbits. There are no adequate and well controlled studies in pregnant women. PROCARDIA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, shortness of breath, diarrhea, constipation, gastrointestinal cramps, flatulence, inflammation, joint stiffness, shakiness, jitteriness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, anemia, leukopenia, purpura, allergic hepatitis, gingival hyperplasia, and erythromelalgia. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Update your echo lab with Cardiac Doppler.

Sonacolor® CD

CARDIAC DOPPLER

The Cardiac Doppler system expands conventional echocardiography by providing noninvasive assessment of flow velocities through all four heart valves. It is all you need to confirm stenotic or regurgitant valvular disease.

- Color spectral patterns grade the degree of valve stenosis and turbulence.
- Valve cross-sectional areas can be derived from pressure gradient half-times.
- Color spectral patterns grade the degree of regurgitation. Valve prolapse is identified through the presence and timing of regurgitation.
- Detects the high velocity jets of flow through prosthetic valves. Detects prosthetic valve leakage. Monitors valve function over time.
- Color spectral patterns locate and grade shunts.
- Displays ECG trace for time reference. Phono trace for correlation of heart sounds with Doppler flow velocity patterns.
- Computes cardiac output approximation, stroke volume and average flow.

Call 1-800-334-4531 to place your order, for in-depth information or an on-site demonstration.

accompanied the increase in blood pressure after cyclosporine treatment: a rise in serum creatinine to values higher than those recorded before transplantation accompanied by low creatinine clearance and a slight increase in plasma volume. Nifedipine induced a larger acute decrease in blood pressure than captopril.

MISCELLANEOUS TOPICS

932 Ventricular Performance in Human Hearts Aged 61 to 73 years

J.V. NIXON, HUGH HALLMARK, KIM PAGE, PETER R. RAVEN, and JERE H. MITCHELL

To determine the response of the older left ventricle to large variations in preload, studies were carried out in 11 subjects, aged 61 to 73 years, who had been carefully screened to rule out latent coronary heart disease. Two-dimensional echocardiograms were recorded before and at the termination of 5 degrees of head-down tilt for 90 minutes and at the termination of graded lower body negative pressure to −40 mm Hg. The older left ventricle conformed to the normal ascending Frank-Starling curve, but compared with changes in younger subjects, showed an altered response to these variations in preload, suggesting an age-related change in diastolic stiffness.

938 Magnetic Resonance Imaging in Pulmonary Arterial Hypertension

ALAIN BOUCHARD, CHARLES B. HIGGINS, BENJAMIN F. BYRD III, EUGENIO G. AMPARO, LUCI OSAKI, and RICHARD AXELROD

Magnetic resonance imaging (MRI) displays the blood pool as very low or no signal intensity so cardiac structures can be visualized without contrast medium. Consequently, MRI was used to examine the right ventricle and pulmonary arteries (PAs) in 17 patients with PA hypertension documented by cardiac catheterization. The study population consisted of 7 patients with primary PA hypertension, 7 patients with Eisenmenger's syndrome and 3 patients with PA hypertension secondary to lung disease. The MRI studies of patients were compared with those from 10 normal volunteers. There was good correlation between end-diastolic right ventricular wall thickness and mean PA pressure ($r = 0.79$). MRI showed enlargement of PAs in all patients with PA hypertension. A magnetic resonance signal was present in the PAs throughout the cardiac cycle in patients with severe PA hypertension (more than 90 mm Hg) in contrast to the absence of signal during systole in normals. Signal within the PA vessels in systole is consistent with decreased flow velocity in patients with severe PA hypertension. MRI was useful in detecting each of the congenital anatomic defects in patients with Eisenmenger's syndrome.

943 Early Cardiac Changes Related to Radiation Therapy

MARKKU J. IKÄHEIMO, KARI O. NIEMELÄ, MARKKU M. LINNALUOTO, MATTI J.T. JAKOBSSON, JUHA T. TAKKUNEN, and PENTTI J. TASKINEN

In 21 women without cardiac disease, postoperative radiation therapy for breast cancer was associated with a transient decrease in left ventricular function measured by echocardiography and systolic time intervals. These changes became normalized within 6 months after therapy. Up to 6 months after therapy, a slight pericardial effusion was found in 33% of the patients.

METHODS

947 Reproducibility of Left Ventricular Area and Volume Measurements Using a Computer Endocardial Edge-Detection Algorithm in Normal Subjects

DONALD A. CONETTA, EDWARD A. GEISER, LESLIE H. OLIVER, ALAN B. MILLER, and C. RICHARD CONTI

A computer endocardial border-detection algorithm was used to determine left ventricular (LV) short-axis area in normal subjects. The LV areas, volumes, and area and volume ejection fraction (EF) were determined from 5 serial recordings in 10 normal subjects in 2 separate echocardiographic laboratories during a 2-week study

FIRST LINE OF DEFENSE

CITRUS FRUIT-PUNCH

When your patients need Potassium Chloride.

K-LYTE/CL®

- effervescent tablets with delicious citrus or fruit-punch flavor
- each tablet in solution provides 25 mEq potassium chloride

K-LYTE/CL® 50

- provides 50 mEq potassium chloride for once-a-day convenience

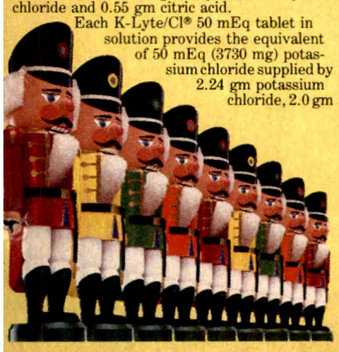
Unmatched safety of liquids, in convenient effervescent tablet form, convenient strengths *and* pleasant-tasting flavors

K-Lyte/Cl Effervescent Tablets Brief Summary

Caution: Federal Law Prohibits Dispensing Without Prescription

DESCRIPTION: Each K-Lyte/Cl® tablet in solution provides the equivalent of 25 mEq (1865 mg) potassium chloride supplied by 1.5 gm potassium chloride, 0.5 gm potassium bicarbonate and 0.91 gm L-lysine monohydrochloride and 0.55 gm citric acid.

Each K-Lyte/Cl® 50 mEq tablet in solution provides the equivalent of 50 mEq (3730 mg) potassium chloride supplied by 2.24 gm potassium chloride, 2.0 gm potassium bicarbonate and 3.65 gm L-lysine monohydrochloride and 1.0 gm citric acid.



INDICATIONS AND USAGE: Therapy or prophylaxis of potassium deficiency.

CONTRAINDICATIONS: Contraindicated in patients with hyperkalemia. Hyperkalemia may complicate chronic renal impairment, metabolic acidosis, acute dehydration, and extensive tissue breakdown. Concomitant administration of potassium salts and potassium-sparing diuretic can produce severe hyperkalemia.

WARNINGS: In patients with impaired potassium excreting mechanisms, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and may be asymptomatic. Use in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

PRECAUTIONS: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. Acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of reduced total body potassium. Therefore, the treatment of potassium depletion requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the ECG, and the clinical status of the patient.

Information for Patients: Patients should be carefully directed to completely dissolve each tablet.

Drug Interactions: Simultaneous administration of potassium supplements and a potassium-sparing diuretic as well as concomitant use of potassium supplements and salt substitutes can result in hyperkalemia (see Contraindications).

Usage in Pregnancy - Pregnancy Category C: It is not known whether K-Lyte products can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity.

Nursing Mothers: There is a potential for serious adverse reactions in nursing infants from oral potassium supplements given to the mother. Nursing or the drug should be discontinued based on the importance of the drug for the mother.

Usage in Children: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most common adverse reactions to oral potassium supplements are nausea, vomiting, diarrhea and abdominal discomfort. These side effects occu more frequently when the medication is not taken with food or is not diluted properly or dissolved completely.

Hyperkalemia occurs only rarely in patients with normal renal function receiving potassium supplements orally.

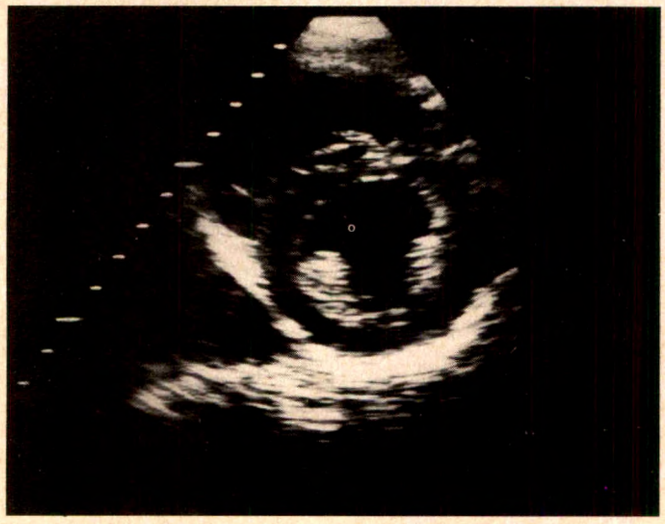
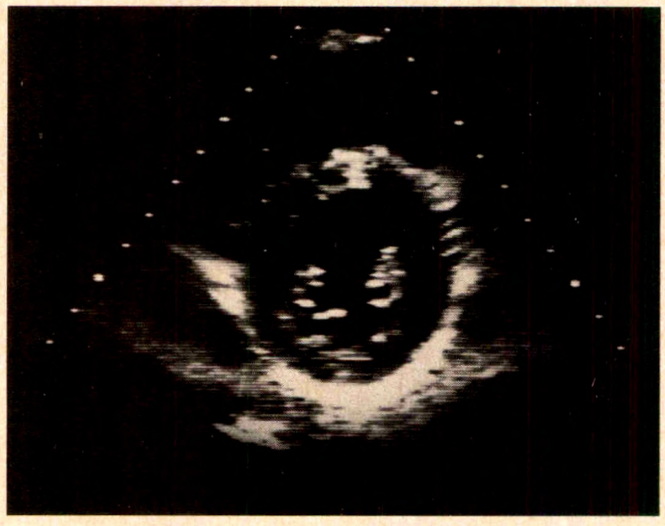
UNIVERSITY OF ILLINOIS LIBRARY

The only difference in Cardioscan's image is the cost.



$25,000 Cardioscan's affordable image looks like this.



$90,000 At more than three times the cost of Cardioscan, their image looks the same.

Until now, sophisticated, high-resolution echocardiography came with a high price tag. To get images like the one at the top you had to pay the cost at the bottom. Interspec has changed all that. We developed Cardioscan™—the easy-to-use echocardiography system that makes high-quality ultrasound imaging not only possible, but *affordable.*

Unlike other low-cost systems, Cardioscan doesn't sacrifice performance for price. You get all the advantages of larger, hospital-scale units—plus, some features often not available even on more expensive systems.

And, Cardioscan has been designed with the future in mind. You do not have to be concerned about your system becoming obsolete as echocardiographic technology advances or your clinical needs change. Your system will be fully upgradeable to keep pace with the demands of your practice.

The best technology packaged in a lightweight, compact design

There is only one way to understand the quality Cardioscan delivers. And that is to compare it with other units. Even when judged against systems costing three times as much, Cardioscan more than measures up.

More reasons to decide on Cardioscan

- Superior image quality and resolution in both 2-D and M-mode.
- Logically grouped, easy-to-learn controls let you concentrate on the patient, not the instrument.
- On-line or off-line calculations capability means calculations and annotations can be performed during patient examinations, or later *in video playback.*
- Triple image memory means you can store up to three images and select the preferred one for calculations and/or hard copy.

- ECG with dual trigger enables automatic viewing of end-systolic and end-diastolic images from the same cardiac cycle.
- Small, lightweight transducer available in a variety of frequencies and focal zones helps make Cardioscan adaptable to a wide range of applications.

The Cardioscan Doppler

In keeping with Interspec's commitment to cardiology, Cardioscan has been designed to accept major upgrades. One of the first of these is the Cardioscan Doppler, which adds noninvasive hemodynamics to your diagnostic capabilities. With pulsed, high PRF, continuous wave and comprehensive calculations, this Doppler is truly state-of-the-art.

Reliable service

Because Cardioscan is made in the U.S., availability of parts is never a problem. A complete service policy includes rapid response to calls and a loaner program to assure maximum up-time.

Compare our image. Compare our price.
Compare our features.
Then contact Interspec today.

period. The area and volume data were statistically analyzed to provide individual and group 95% confidence limits for determining the percent difference between serial, end-systolic and end-diastolic areas and volumes, area and volume EF. The limits for end-diastolic volume (±16.7%) were similar to, while those for end-systolic volume (±17%) and volume EF (±9.7) were narrower than, those previously recorded. This computer analysis of echocardiographic LV indexes may provide a more sensitive method for detecting change of serially recorded echoes in patients.

953 Nd-YAG Laser Fusion of Human Atheromatous Plaque-Arterial Wall Separations in Vitro

JOHN F. HIEHLE Jr., DONNA B.C. BOURGELAIS, STANLEY SHAPSHAY, FREDERICK J. SCHOEN, DUCKSOO KIM, and J. RICHARD SPEARS

The efficacy of a new technique, laser balloon angioplasty, for treatment of arterial dissections was tested in human postmortem atherosclerotic arteries. Separated layers of plaque and underlying arterial wall were juxtaposed and 17 W of neodymium-yttrium aluminum garnet laser radiation were directed perpendicularly to the luminal surface for 5 to 32 seconds over a nominal spot size of approximately 4 mm^2. Depending on lasing duration, satisfactory tissue welds (supporting loads up to 25 g) could be achieved when external pressure was applied to the tissues during lasing and when blood was present within the dissected plane. This technique was also successfully applied during postmortem balloon angioplasty with a prototype balloon within which a laser-transmitting optical fiber terminated in a diffusing tip for lateral dispersion of laser energy. The improved luminal geometry afforded by application of this catheterization technique may be useful for treatment of spontaneous and balloon angioplasty–induced arterial dissections.

CARDIOVASCULAR PHARMACOLOGY

958 Circulatory Effects of Coffee in Relation to the Pharmacokinetics of Caffeine

PAUL SMITS, THEO THIEN, and ALBERT van't LAAR

In 8 normotensive subjects, circulatory parameters were studied after intervention with coffee in 2 strengths, decaffeinated coffee and hot water after a caffeine abstinence of 4.5 times the individual caffeine half-life. Drinking regular and strong coffee resulted in a similar increase in systolic and especially in diastolic blood pressure (±15%), whereas increases in forearm blood flow and plasma epinephrine were less pronounced. After ingestion of decaffeinated coffee, a small increase in diastolic blood pressure was seen, and after drinking water no changes were observed. In another group of 30 normotensive subjects, a negative correlation was ascertained between the coffee-induced increase in blood pressure and basal plasma caffeine level ($r = -0.71$, $p < 0.001$). It is concluded that with chronic caffeine intake during daily life, subjects in whom the plasma caffeine half-life is short are exposed to a pressor response after drinking coffee despite the phenomenon of adaptation as described in published reports.

EXPERIMENTAL STUDIES

964 Beta-Adrenergic Stimulation Reverses Postischemic Myocardial Dysfunction Without Producing Subsequent Functional Deterioration

ROBERTO BOLLI, WEI-XI ZHU, MARY LEE MYERS, CRAIG J. HARTLEY, and ROBERT ROBERTS

The prolonged myocardial dysfunction observed after reversible ischemia (stunned myocardium) has been attributed to inability of myocytes to replenish ATP stores. Accordingly, inotropic stimulation should produce little or no increase in function. To test this hypothesis, systolic wall thickening, an index of regional myocardial function, was measured ultrasonically in open-chest dogs undergoing 15 minutes of occlusion of the left anterior descending coronary artery (LAD) followed by 4 hours of reperfusion. Three hours after reperfusion, function in the LAD-dependent territory was still severely depressed (12.3 ± 16.1% of baseline). Isoproterenol (0.1 mg/kg/min intravenously) increased function to values similar to baseline. Discontinuation of isoproterenol was associated with return of function to pre-isoproterenol levels. Thus, stunned myocardium responds dramatically to β-adrenergic stimulation without subsequent adverse effects on function in the short term. The data indicate that stunned myocardium is inherently capable of generating ATP and do not support the view that an inability to replenish ATP stores causes postischemic dysfunction.

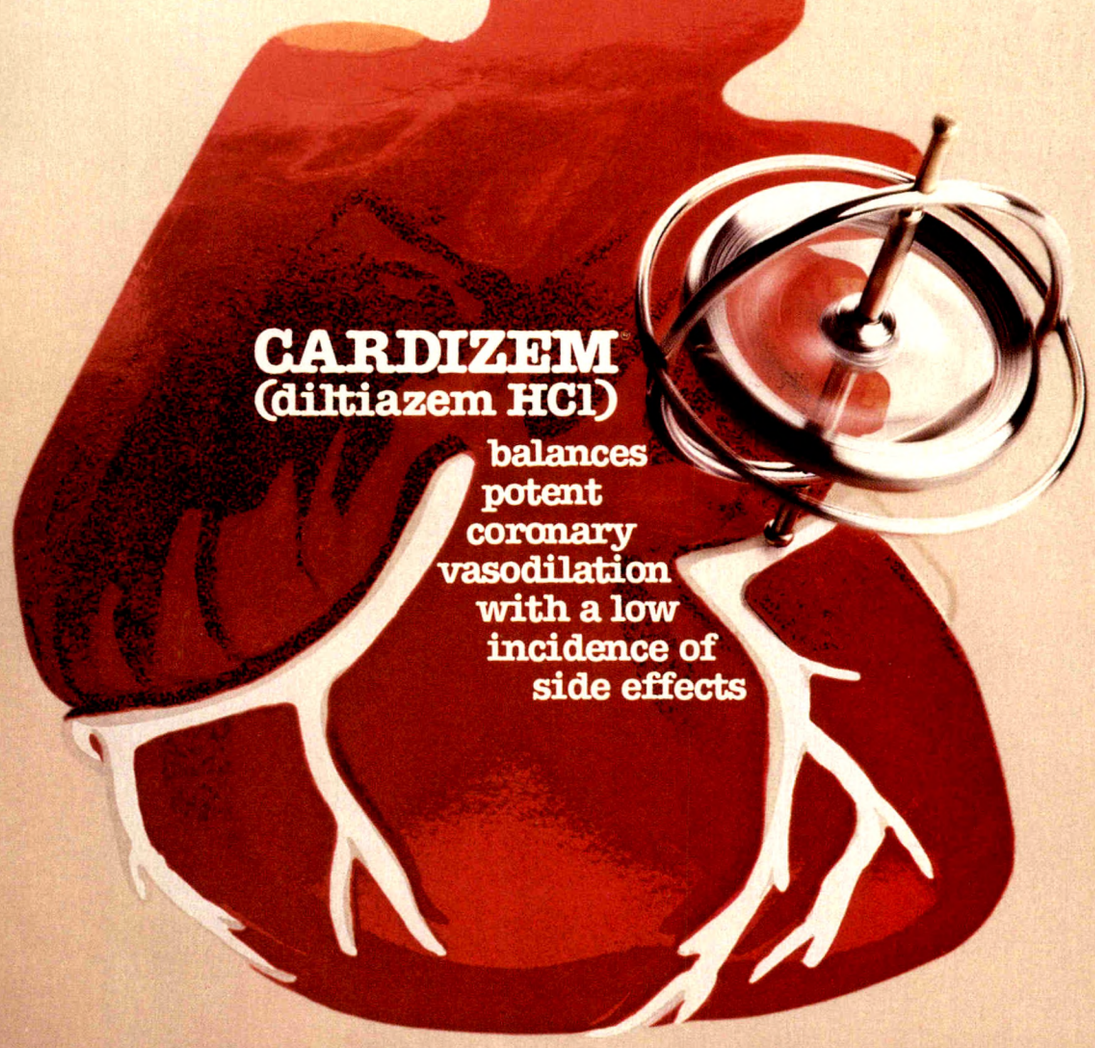
BALANCED CALCIUM CHANNEL BLOCKADE!



CARDIZEM®
(diltiazem HCl)

balances potent coronary vasodilation with a low incidence of side effects

Low incidence of side effects
CARDIZEM® (diltiazem HCl) produces an incidence of adverse reactions not greater than that reported with placebo therapy, thus contributing to the patient's sense of well-being.

*Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm and in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

Reduces angina attack frequency*
42% to 46% decrease reported in multicenter study.[1]

Increases exercise tolerance*
In Bruce exercise test,[2] control patients averaged 8.0 minutes to onset of pain; Cardizem patients averaged 9.8 minutes ($P<.005$).

CARDIZEM®
(diltiazem HCl)

THE BALANCED CALCIUM CHANNEL BLOCKER

Please see full prescribing information on following page.

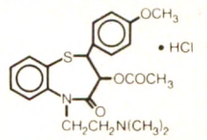
2/84

PROFESSIONAL USE INFORMATION

cardizem®
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM® (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy) -5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem hydrochloride for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanisms of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance, probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate-blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina. CARDIZEM has been effective in controlled trials in reducing angina frequency and increasing exercise tolerance.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, patients receiving CARDIZEM have exhibited reversible acute hepatic injury as evidenced by moderate to extreme elevations of liver enzymes. (See PRECAUTIONS and ADVERSE REACTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS).

Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities. In healthy volunteers, diltiazem has been shown to increase serum digoxin levels up to 20%.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%), AV block (1.1%). In addition, the following events were reported infrequently (less than 1%) with the order of presentation corresponding to the relative frequency of occurrence.

Cardiovascular:	Flushing, arrhythmia, hypotension, bradycardia, palpitations, congestive heart failure, syncope.
Nervous System:	Paresthesia, nervousness, somnolence, tremor, insomnia, hallucinations, and amnesia.
Gastrointestinal:	Constipation, dyspepsia, diarrhea, vomiting, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH.
Dermatologic:	Pruritus, petechiae, urticaria, photosensitivity.
Other:	Polyuria, nocturia.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: erythema multiforme; leukopenia; and extreme elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experience with oral diltiazem has been limited. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral/LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. Although individual patients may respond to any dosage level, the average optimum dosage range appears to be 180 to 240 mg/day. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents:

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

Cardizem 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1771-49). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1772-49). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

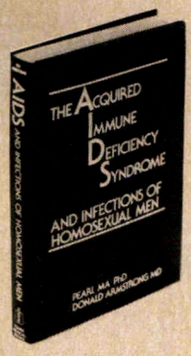
AIDS

An important new book on today's most virulent epidemic



From the Publishers of The American Journal of Medicine, The American Journal of Surgery, and Cutis

Acquire Immune Deficiency Syndrome (AIDS) and Infections of Homosexual Men

edited by **Pearl Ma, PhD,** and **Donald Armstrong, MD** with a foreword by **David J. Sencer, MD,** *Commissioner of Health, New York City; formerly Director, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services*
0-914316-38-9, 442 pages, illus., 1984, $39.50

The first scientific presentation to review all the facts in full

AIDS has become one of the most publicized diseases in modern times. It has produced fear and confusion in the general public and presented a formidable challenge to the medical community. Physicians and scientists have begun work on managing this epidemic, disease control centers continue to search for answers, and the federal government has declared AIDS the number one health priority of the nation. Understanding this disease demands cooperation between many different medical specialties, and papers on this subject have been published in many diverse journals not regularly read by individual specialists. Now, for the first time, two highly distinguished medical experts, Drs. Pearl Ma and Donald Armstrong, have coordinated in one easily accessible volume the complete range of interdisciplinary approaches to this complex disease, with contributions by the most eminent researchers and physicians in disease control and hospital teaching centers throughout the country. Comprehensive coverage is given to the entire spectrum of sexually transmitted diseases, and an additional section on diagnostic perspectives offers never before published material on why this syndrome occurs primarily among homosexual men. For any physician or other health care professional interested in the prevention and cure of this modern epidemic, this book is an indispensable guide to recognizing and treating AIDS and other sexually transmitted diseases.

Table of Contents

• PART I SEXUALLY TRANSMITTED DISEASES — NONDIARRHEAL • PART 2 SEXUALLY TRANSMITTED DISEASES — DIARRHEAL • PART 3 OTHER SEXUALLY TRANSMITTED DISEASES • PART 4 INFECTIOUS AND NEOPLASTIC COMPLICATIONS OF AIDS • PART 5 IMMUNOLOGICAL EVALUATION METHODS AND CONTROLS • PART 6 DIAGNOSTIC PERSPECTIVE

Crafted entirely in gold, the reliquary bears an eloquent inscription extolling the virtue of Anne, Duchess of Brittany and Queen of France. The reliquary dates from 1513.

dipyridamole Tablets of 25, 50 and 75 mg

Persantine®

The experienced dipyridamole

BRIEF SUMMARY

INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency of, or eliminate, anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.
PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.
ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.
DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy. Tablets of 25, 50 and 75 mg. For complete details, please see the full prescribing information.

Cardiac Bioprostheses

Proceedings of the Second International Symposium
Rome, Italy, May 17-19, 1982

The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609pp., illus., 1982, $69.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much **current** information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening **today.**

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a **must buy!** It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of **Modern Techniques in Surgery** and co-author of the new annual, **Cardiology,** now available in its second issue, **Cardiology 1982.**

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

THE UNIVERSITY OF CALGARY

Head Division of Cardiology

Applications are invited for the position of Head, Division of Cardiology, Department of Medicine at The University of Calgary. The person selected will also be Chief, Division of Cardiology at Foothills Hospital, Southern Alberta's major referral and teaching hospital. Interested applicants should be qualified in medicine and hold the Fellowship of the Royal College of Physicians and Surgeons of Canada or an equivalent recognized certification. In addition to clinical qualifications, applicants should have administrative experience and will be expected to develop an independent research program. The rank and salary level will be in the full Professor range; however, an Associate Professor could be considered.

All qualified individuals are encouraged to apply, but preference will be given to Canadian citizens and permanent residents. Deadline for receipt of applications is December 31, 1985.

Please send curriculum vitae and the names of three referees to:

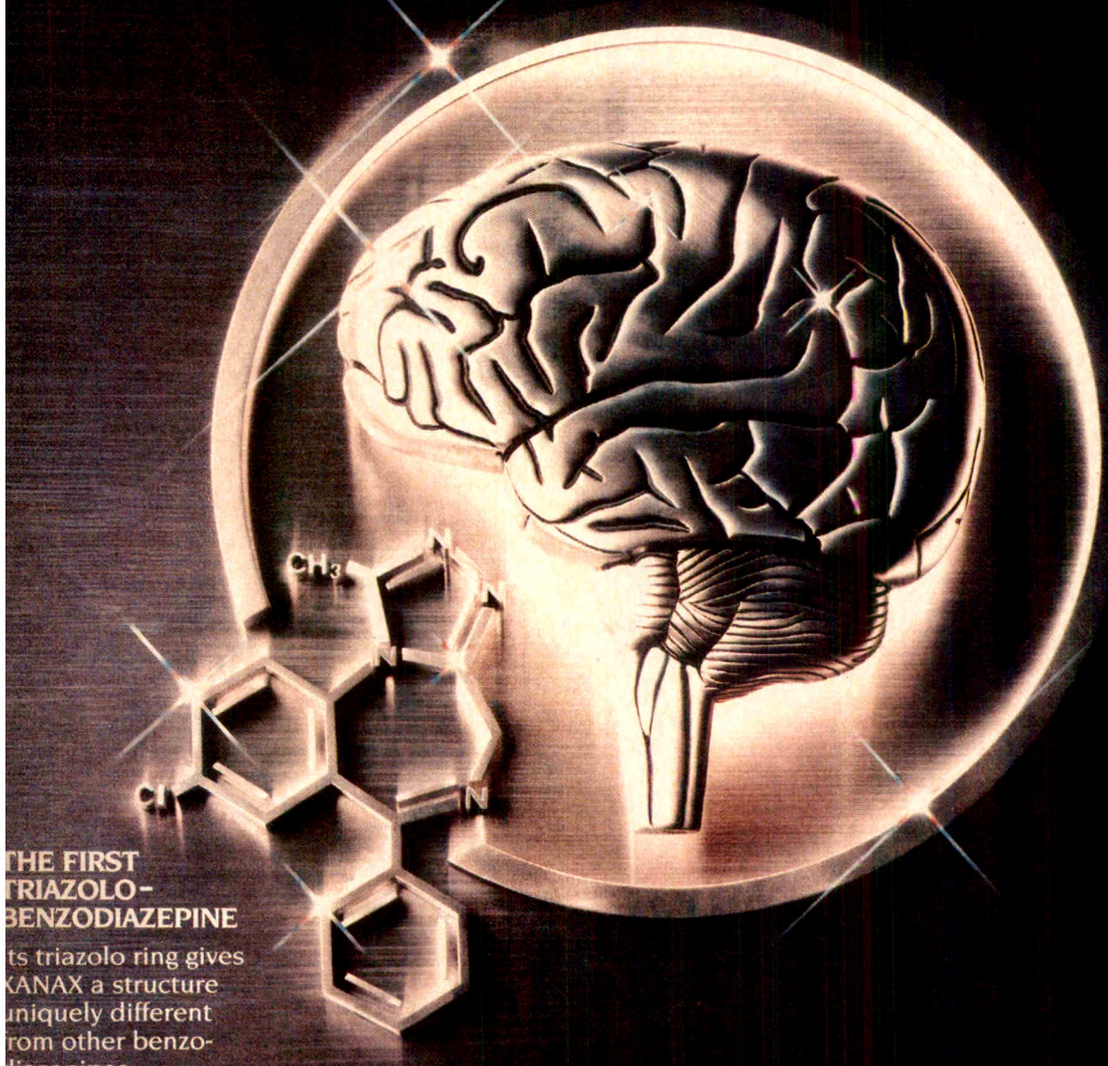
Xanax® 0.5 mg Tablets

alprazolam C-IV



THE FIRST TRIAZOLO-BENZODIAZEPINE

ts triazolo ring gives XANAX a structure uniquely different rom other benzo-diazepines.

THE FIRST OF A UNIQUE CLASS

Upjohn

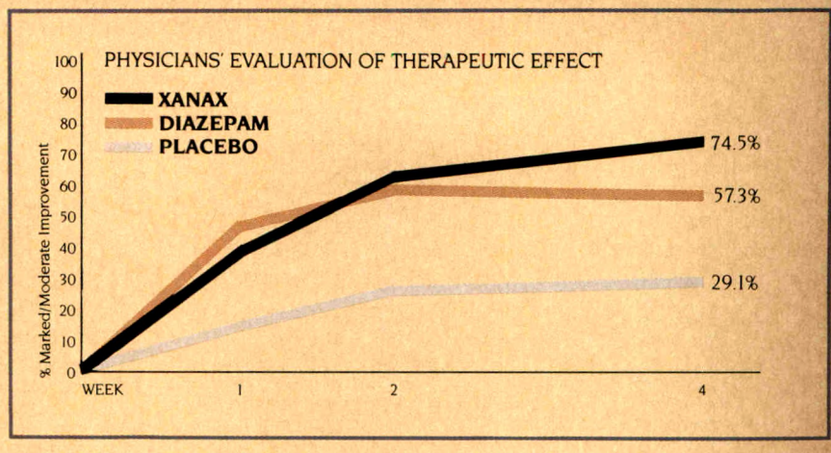
© 1985 The Upjohn Company

FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam.*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy in *a 976-patient*, placebo-controlled, multicenter study.*

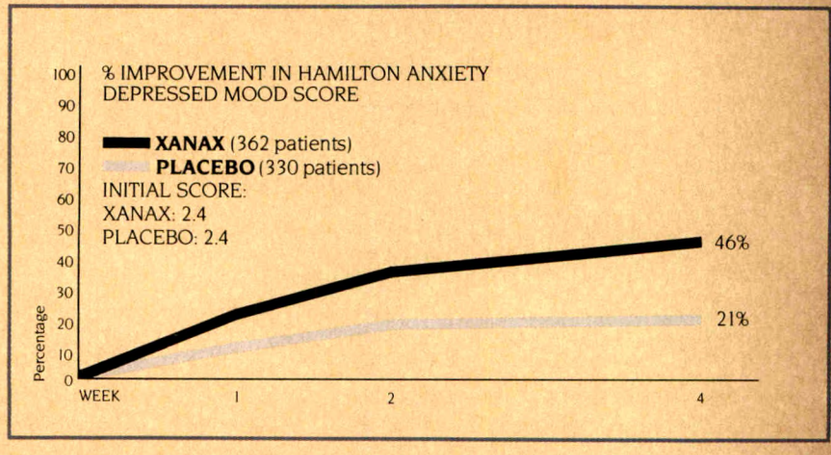


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE: XANAX 0.25–0.5 mg T.I.D.

The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets

alprazolam Ⓒ IV

XANAX® Tablets
(alprazolam)

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation. (See Drug Interaction section.) Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage. (See Dosage and Administration.) Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other side effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

DOSAGE AND ADMINISTRATION
The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than one milligram every three days.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION. B-3-S

969 Myocardial Kinetics of Thallium-201 After Stress in Normal and Perfusion-Reduced Canine Myocardium
ROBERT D. OKADA

Eleven mongrel dogs with experimental left anterior descending coronary stenoses were given thallium during norepinephrine infusion to simulate exercise. The infusion was then discontinued and thallium activity monitored regionally using miniature radiation detectors for 3 hours. The mean fractional myocardial thallium clearance was lower (0.47 ± 0.03 [± standard error of the mean]) for the stenosis zone compared to the no-stenosis zone (0.57 ± 0.03) ($p < 0.0001$). The stress blood flow ratio (stenosis/no-stenosis zone = 0.27 ± 0.06) was significantly lower than the final thallium activity ratio (0.68 ± 0.07) ($p < 0.001$), consistent with thallium redistribution occurring over the 3-hour period. In conclusion, myocardial thallium kinetics has been described in an exercise-simulated dog model. The fractional clearance of thallium can differentiate myocardium distal to a coronary vessel stenosis from that supplied by a normal coronary vessel.

974 Relation of Myocardial Salvage to Size of Myocardium at Risk in Dogs
ANDREW ZALEWSKI, SHELDON GOLDBERG, DUARTE B. FARIA, RICHARD KROL, and PETER R. MAROKO

The relation between the size of myocardium at risk and the magnitude of myocardial salvage with different pharmacologic interventions was studied. Open-chest, anesthetized dogs underwent left anterior descending coronary artery occlusion; 15 minutes after ligation they were treated with 5 different pharmacologic interventions. Retrospectively, the dogs were separated into 2 subgroups: those with small risk area, i.e., more than 15% of the left ventricle, and those with large risk area, i.e., more than 15% of the left ventricle. Heart rate and mean arterial pressure were similar between the 2 groups throughout the 6-hour experiments. In the subgroup with a small risk area, significantly more myocardium was salvaged than in the subgroup with large risk area. There was a close inverse correlation between the size of the area at risk and myocardial salvage. Thus, the initial size of the area at risk is an important determinant of the effectiveness of various treatments in reducing infarct size.

978 Usefulness of Defibrotide in Protecting Ischemic Myocardium from Early Reperfusion Damage
CHRISTOPH THIEMERMANN, PETRA LÖBEL, and KARSTEN SCHRÖR

Reperfusion of an occluded coronary vessel after ischemia initially leads to further tissue injury, including early reperfusion arrhythmias. Cats were subjected to 3 hours of coronary artery ligation followed by 2 hours of reperfusion. Compared with sham-operated cats, there was a considerable loss of CK-specific activity from the ischemic myocardium and electrocardiographic signs of myocardial necrosis. Treatment with defibrotide, starting at 30 minutes after coronary occlusion, largely protected from tissue damage as seen in the 60% inhibition of CK loss, inhibition of ST-segment elevations and prevention of Q-wave enlargement in the electrocardiogram. Defibrotide also antagonized ischemia-induced platelet activation and secretion, prevented fatal arrhythmias and was found to stimulate prostacyclin formation in a separate set of experiments. These data indicate beneficial cardioprotective actions of this new compound in myocardial reperfusion damage.

983 The Healing Process in Normal Canine Arteries and in Atherosclerotic Monkey Arteries After Transluminal Laser Irradiation
GEORGE S. ABELA, FILIPPO CREA, JAMES E. SEEGER, DAISEY FRANZINI, ALBERT FENECH, SIGURD J. NORMANN, ROBERT L. FELDMAN, CARL J. PEPINE, and C. RICHARD CONTI

The immediate and short-term response of normal and atherosclerotic arteries was studied in dogs and monkeys. Lasing was done via a fiber-catheter delivery system in an intact circulation. To maximize wall injury, the arteries were lased at an acute angle to the arterial wall. Evaluation of the effects using angiographic and histologic

Continued on page A34

examinations were made at 1 hour and at 2, 4, 7, 14, 30 and 60 days. The data show that lasing of the arterial wall results in discrete spots. They might occur inadvertently while attempting laser angioplasty, but they heal completely by 30 days after lasing.

989 Validation of Instantaneous Pressure Gradients Measured by Continuous-Wave Doppler in Experimentally Induced Aortic Stenosis

MARK J. CALLAHAN, A. JAMIL TAJIK, QIAN SU-FAN, and ALFRED A. BOVE

In 8 dogs, an ascending aortic snare was adjusted to produce left ventricular (LV) outflow gradients from 4 to 179 mm Hg. Pressure-tip transducer catheters recorded LV and aortic pressures simultaneously with a continuous-wave Doppler signal. In 120 randomly selected sinus beats, Doppler-derived maximal gradient correlated well with maximal instantaneous catheter gradient ($r = 0.99$). Mean gradients were also closely related. For gradients greater than 100 mm Hg, the correlation remained good ($r = 0.98$), but for gradients less than 50 mm Hg, the correlation was not as precise ($r = 0.81$). No correlation was observed between the timing of maximal Doppler velocity and either maximal or mean catheter gradient. All 120 cycles were digitized at 10-m/s intervals throughout systole. For the 2,742 pairs of points so obtained, the correlation was excellent ($r = 0.95$). These results provide further validation of the use of continuous-wave Doppler in the assessment of maximal mean and instantaneous gradients.

For hypertensive emergency

TRANDATE® INJECTION 20 ml, 5 mg/ml

labetalol HCl/Glaxo

The "beta-dilator"™ response: control within minutes

Action within a minute. Trandate® (labetalol HCl/Glaxo) Injection rapidly, predictably lowers blood pressure by lowering total peripheral resistance (TPR), while maintaining cardiac output.[1,2] The "beta-dilator"™ effect of simultaneous beta blockade and alpha blockade-induced vasodilation is apparent within a minute.

Rapid control. Full effect of an IV dose is apparent in 5 to 10 minutes: helps avoid hypotensive "overshoot," facilitates monitoring.

Cost control. Rapid effect may shorten hospital stay and beneficially affect costs under DRG's.

Well tolerated.* The most commonly reported adverse reactions: postural hypotension,† dizziness,† paresthesias, increased sweating and nausea.

Smooth transition to oral therapy with the same agent. Control of hypertensive crisis with Trandate Injection allows continued control on oral therapy with no need to change agents.

Trandate Injection—the "beta-dilator"™ response to hypertensive emergencies...another original product of Glaxo research.

* Patients should always be kept in a supine position during IV drug administration. See **DOSAGE AND ADMINISTRATION** section of Prescribing Information before initiating therapy.

† The episodes of postural hypotension and dizziness occurred primarily in one study in which patients were placed in an upright position within three hours of dosing for evaluation.

For a discussion of **ADVERSE REACTIONS**, please see Brief Summary of Prescribing Information on the last page of this advertisement.

Glaxo

For hypertensive emergency

TRANDATE® INJECTION 20 ml, 5 mg/ml

labetalol HCl/Glaxo

The "beta-dilator"™ response: control within minutes

- Trandate Injection can be administered as repeated IV injections, or by continuous infusion
- After initial dosing, further blood pressure reductions can be achieved with additional injections or by slow continuous infusion
- Discontinue Trandate Injection when blood pressure goal is achieved—when supine blood pressure has begun to rise, oral therapy may be initiated
- Patients should be kept in the supine position during IV drug administration. See **DOSAGE AND ADMINISTRATION** section of Prescribing Information before initiating therapy

For a discussion of **ADVERSE REACTIONS**, please see Brief Summary of Prescribing Information on the last page of this advertisement.

TRANDATE® Injection
(labetalol hydrochloride)

BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS AND USAGE: TRANDATE® (labetalol HCl) Injection is indicated for control of blood pressure in severe hypertension.

CONTRAINDICATIONS: TRANDATE® Injection is contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS: Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitilization and diuretic, TRANDATE® therapy should be withdrawn (gradually, if possible).

Ischemic Heart Disease: Angina pectoris has not been reported upon labetalol HCl discontinuation. However, following abrupt cessation of therapy with some beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TRANDATE is planned, the patient should be carefully observed and should be advised to limit physical activity. If angina markedly worsens or acute coronary insufficiency develops, TRANDATE administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken.

Nonallergic Bronchospasm (eg, chronic bronchitis and emphysema): Since TRANDATE Injection at the usual intravenous therapeutic doses has not been studied in patients with nonallergic bronchospastic disease, it should not be used in such patients.

Pheochromocytoma: Intravenous labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma; higher than usual doses may be required. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (eg, tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heartbeat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

Rapid Decreases of Blood Pressure: Caution must be observed when reducing severely elevated blood pressure. Although such findings have not been reported with intravenous labetalol HCl, a number of adverse reactions, including cerebral infarction, optic nerve infarction, angina and ischemic changes in the electrocardiogram, have been reported with other agents when severely elevated blood pressure was reduced over time courses of several hours to as long as 1 or 2 days. The desired blood pressure lowering should therefore be achieved over as long a period of time as is compatible with the patient's status.

PRECAUTIONS: General: ***Impaired hepatic function*** may diminish metabolism of TRANDATE® Injection.

Hypotension: Symptomatic postural hypotension (incidence 58%) is likely to occur if patients are tilted or allowed to assume the upright position within 3 hours of receiving TRANDATE Injection. Therefore, the patient's ability to tolerate an upright position should be established before permitting any ambulation.

Jaundice or Hepatic Dysfunction: On rare occasions, oral labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients: The following information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. During and immediately following (for up to 3 hours) TRANDATE Injection, the patient should remain supine. Subsequently, the patient should be advised on how to proceed gradually to become ambulatory, and should be observed at the time of first ambulation.

When the patient is started on TRANDATE Tablets, following adequate control of blood pressure with TRANDATE Injection, appropriate directions for titration of dosage should be provided (see **DOSAGE AND ADMINISTRATION**).

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted: While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with TRANDATE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with TRANDATE Tablets should consult a physician at any sign of impending cardiac failure. Also transient scalp tingling may occur, usually when treatment with TRANDATE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests: Routine laboratory tests are ordinarily not required before or after intravenous labetalol HCl. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions: Since TRANDATE (labetalol HCl) Injection may be administered to patients already being treated with other medications, including other antihypertensive agents, careful monitoring of these patients is necessary to detect and treat promptly any undesired effect from concomitant administration.

In one survey, 2.3% of patients taking labetalol HCl orally in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown, but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl administered orally. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions: The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C: Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the MRHD, respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery: Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers: Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when TRANDATE® (labetalol HCl) Injection is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: TRANDATE® Injection is usually well tolerated. Most adverse effects have been mild and transient and, in controlled trials involving 92 patients, did not require labetalol HCl withdrawal. Symptomatic postural hypotension (incidence 58%) is likely to occur if patients are tilted or allowed to assume the upright position within 3 hours of receiving TRANDATE Injection. Moderate hypotension occurred in 1 of 100 patients while supine. Increased sweating was noted in 4 of 100 patients, and flushing occurred in 1 of 100 patients.

The following also were reported with TRANDATE Injection with the incidence per 100 patients as noted:

Cardiovascular System: Ventricular arrhythmia in 1.

Central and Peripheral Nervous Systems: Dizziness in 9; tingling of the scalp/skin in 7; hypoesthesia (numbness) and vertigo in 1 each.

Gastrointestinal System: Nausea in 13; vomiting in 4; dyspepsia and taste distortion in 1 each.

Metabolic Disorders: Transient increases in blood urea nitrogen and serum creatinine levels occurred in 8 of 100 patients; these were associated with drops in blood pressure, generally in patients with prior renal insufficiency.

Psychiatric Disorders: Somnolence/yawning in 3.

Respiratory System: Wheezing in 1.

Skin: Pruritus in 1.

The incidence of adverse reactions depends upon the dose of labetalol HCl. The largest experience is with oral labetalol HCl (see TRANDATE Tablet Product Information for details.) Certain of the side effects increased with increasing oral dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are probably or possibly dose-related.

Labetalol HCl Daily Dose (mg)	**200**	**300**	**400**	**600**	**800**	**900**	**1200**	**1600**	**2400**
Number of Patients	522	181	606	608	503	117	411	242	175
Dizziness (%)	2	3	3	3	5	1	9	13	16
Fatigue	2	1	4	4	5	3	7	6	10
Nausea	<1	0	1	2	4	0	7	11	19
Vomiting	0	0	<1	<1	<1	0	1	2	3
Dyspepsia	1	0	2	1	1	0	2	2	4
Paresthesias	2	0	2	2	1	1	2	5	5
Nasal Stuffiness	1	1	2	2	2	2	4	5	6
Ejaculation Failure	0	2	1	2	3	0	4	3	5
Impotence	1	1	1	1	2	4	3	4	3
Edema	1	0	1	1	1	0	1	2	2

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl during investigational use and extensive foreign marketing experience.

Clinical Laboratory Tests: Among patients dosed with TRANDATE Tablets, there have been reversible increases of serum transaminases in 4% of patients tested and, more rarely, reversible increases in blood urea.

OVERDOSAGE: Overdosage with TRANDATE® Injection causes excessive hypotension which is posture sensitive and, sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: **Excessive bradycardia**—administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. **Cardiac failure**—administer a digitalis glycoside and a diuretic. **Hypotension**—administer vasopressors, eg, norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. **Bronchospasm**—administer a $beta_2$-stimulating agent and/or a theophylline preparation.

If overdosage with labetalol HCl follows oral ingestion, gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 g/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION: Initiation of Dosing with TRANDATE Tablets: Subsequent oral dosing with TRANDATE Tablets should begin when it has been established that the supine diastolic blood pressure has begun to rise. The recommended initial dose is 200 mg, followed in 6-12 hours by an additional dose of 200 mg or 400 mg, depending on the blood pressure response. Thereafter, **inpatient titration with TRANDATE Tablets may proceed as follows:**

Inpatient Titration Instructions

Regimen	Daily Dose*
200 mg bid	400 mg
400 mg bid	800 mg
800 mg bid	1600 mg
1200 mg bid	2400 mg

*If needed, the total daily dose may be given in three divided doses.

While in the hospital, the dosage of TRANDATE (labetalol HCl) Tablets may be increased at one-day intervals to achieve the desired blood pressure reduction.

For subsequent outpatient titration or maintenance dosing see TRANDATE Tablets Product Information **DOSAGE AND ADMINISTRATION** for additional recommendations.

HOW SUPPLIED: TRANDATE® Injection, 5 mg/ml, is supplied in 20 ml (100 mg) ampules, box of 1 (NDC 0173-0350-59).

Store between 2° and 30° C (36° and 86° F.) Do not freeze.

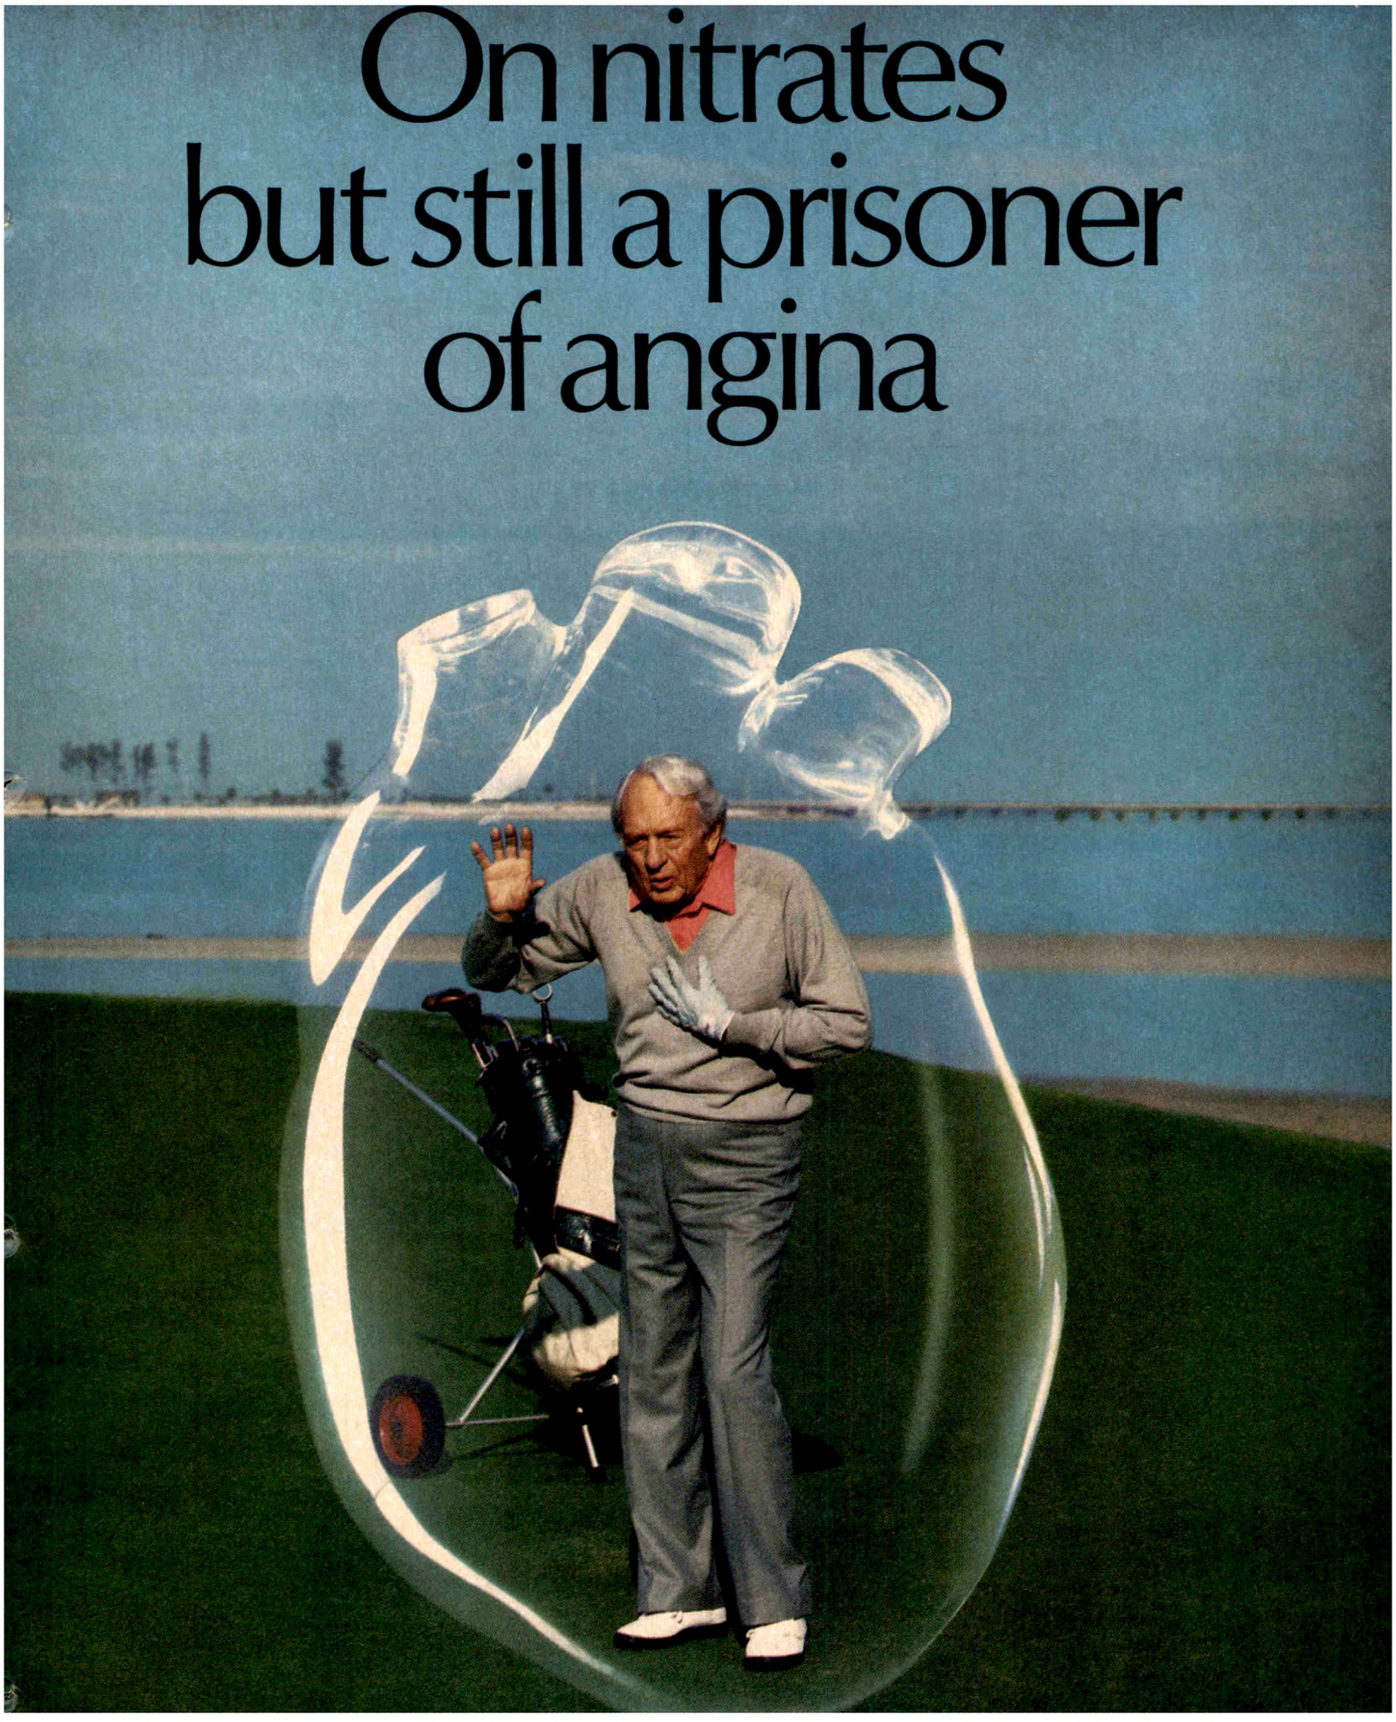
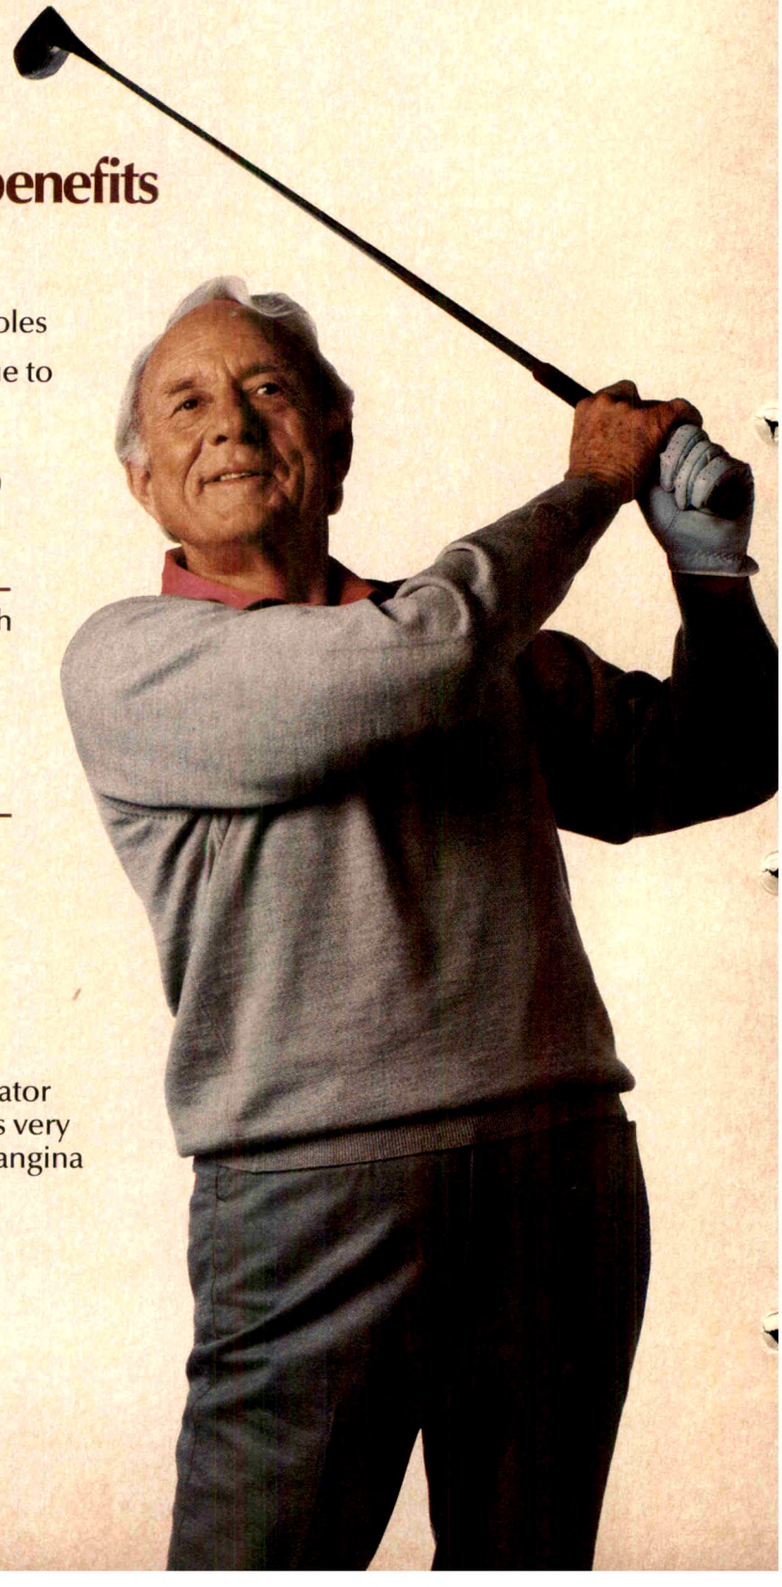
On nitrates but still a prisoner of angina



When nitrates alone are not enough

Add **Calan®** *TABLETS*
80 mg and 120 mg
(verapamil HCl)



Calan plus nitrates: Unique hemodynamic benefits

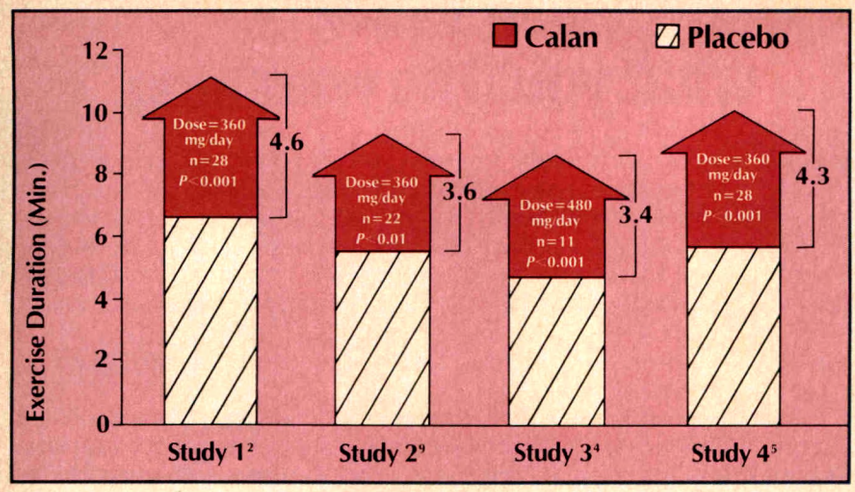
- increased myocardial oxygen supply—prevents vasoconstriction both in large coronary arteries and in coronary arterioles
- reduced myocardial oxygen demand due to
  - —a reduction in peripheral vascular resistance (afterload)
  - —a decrease in venous return (preload)
  - —a modest decrease in contractility

"It makes sense to treat those patients [with chronic stable angina]... [with] an agent that has a beneficial effect on both oxygen demand and supply, rather than a beta blocker which attacks just one side of that ratio."[1]

Calan plus nitrates: Efficacy for all types of angina

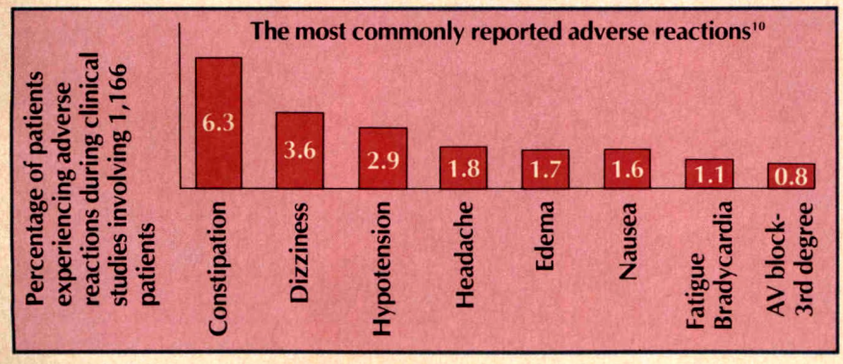
"...a combination of rate-lowering vasodilator (verapamil...) and long-acting nitrates... is very efficacious in patients with variant angina, angina of effort, and unstable angina at rest."[1]

Calan efficacy: Significant improvement in exercise tolerance[2-9]



- clinically significant improvement in exercise tolerance
- clinically significant reduction in the number of attacks and the need for sublingual nitroglycerin

Calan safety: Favorable side-effects profile



With Calan, side effects such as fatigue, mental depression, impotence or bradycardia (heart rate less than 50 beats/min) seldom occur.

In one study involving 63 patients "verapamil therapy was not discontinued in any patient because of the development of adverse reactions."[8]

Calan® *TABLETS*
80 mg and 120 mg
(verapamil HCl)

SEARLE

Please see following page for a brief summary of the complete prescribing information.

5W001T

Calan® **TABLETS**
80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block.
Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension, usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Elevations of liver enzymes have been reported. Four cases have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually DC-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.
Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use.
Adverse Reactions: Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, spotty menstruation, ecchymosis, bruising, gynecomastia, and psychotic symptoms. Overall continuation rate was 94.5% in 1,166 patients.

If you like what you're reading, you'll love what you'll be watching

The American Journal of Cardiology does more than just print the best in authoritative articles on cardiovascular treatment. Now it puts them on videotape.

Hosted by Editor-in-Chief William C. Roberts, MD, *AJC Video Report* will feature lively, highly-visualized discussions with noted cardiovascular specialists and authors of the most important articles appearing each month in *The American Journal of Cardiology.* And it will extend the utility of the articles by exploring their application in clinical practice.

Each of the 45 minute videocassettes will feature a special guest panelist as well as the guest authors discussing:

• Coronary Heart Disease • Arrhythmias and Conduction Disturbances • Systemic Hypertension • Congestive Heart Failure • Valvular Heart Disease • Cardiomyopathy • Congenital Heart Disease • Cardiovascular Pharmacology and • Experimental Studies

AJC Video Report will be produced on a regular monthly basis starting January, 1986.

TO RECEIVE every copy of AJC Video Report—at the special introductory subscription price of $395* for 12 cassettes—complete this coupon and send it to: Joyce Sturges, *AJC Video Report,* The Yorke Medical Group, 875 Third Avenue, New York, N.Y. 10022. Or call (212) 605-9549.

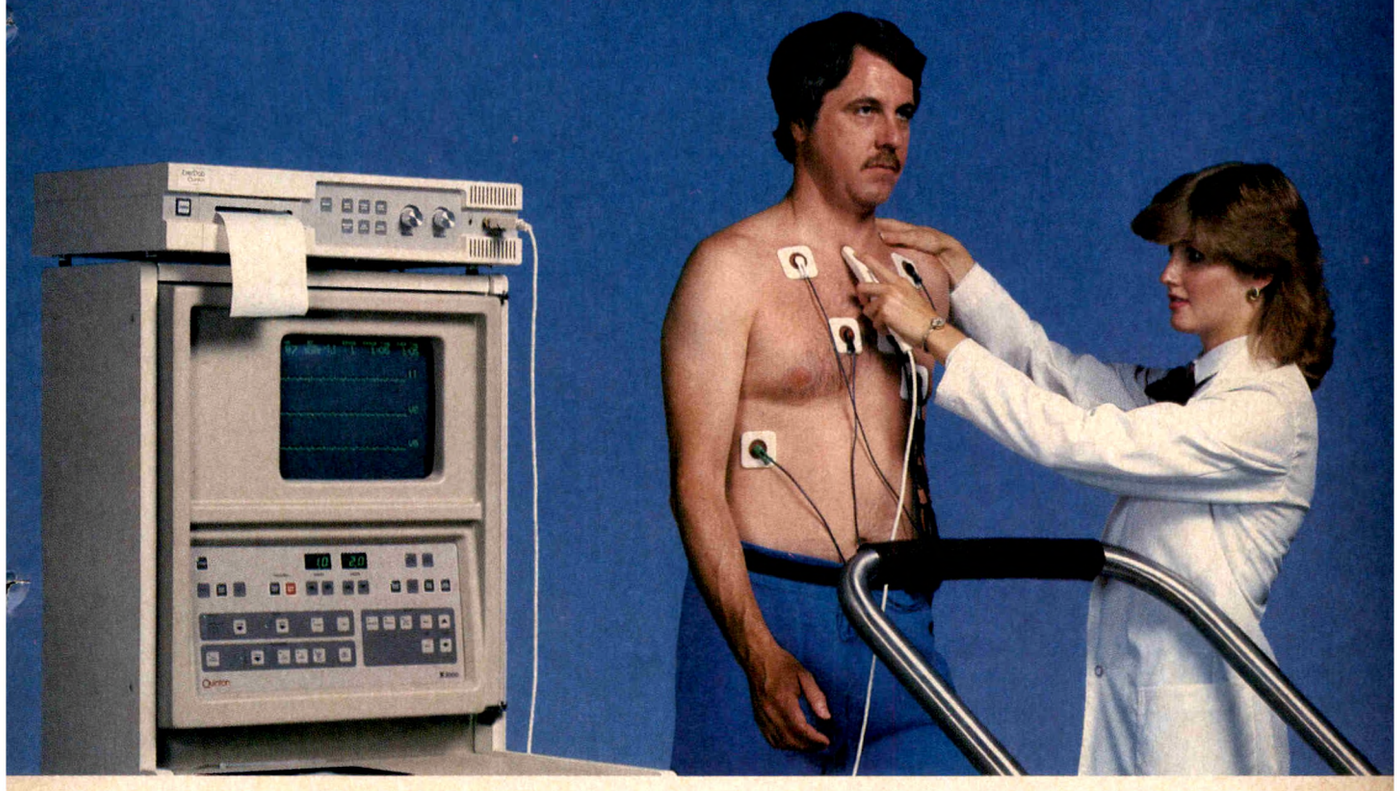
The American Journal of Cardiology

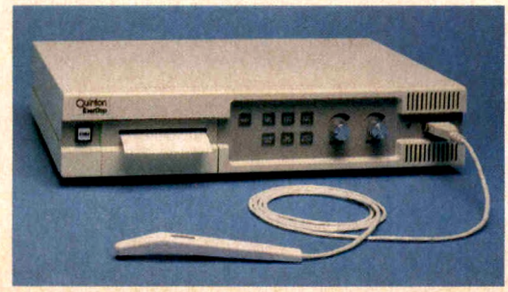
Introducing a Noninvasive Method for Assessing Left Ventricular Function



Quinton Instrument Company is proud to announce *ExerDop*. . . the new diagnostic tool that makes ventricular function assessment inexpensive, free of radiation risks, and technically simple—all advantages over radioisotope methods.

The velocity and acceleration of blood ejected from the left ventricle are reliable indicators of ventricular function. In fact, a growing body of evidence points to peak acceleration as its most sensitive indicator. **ExerDop** is the only continuous wave Doppler instrument capable of recording *instantaneous peak velocity, peak acceleration, and stroke distance* on a beat-to-beat basis. Data is printed out immediately after each heartbeat and the tabular final report summarizes data sets and percentage changes.

Many cardiologists evaluate the deterioration of a patient's ventricular function under stress prior to making surgical decisions regarding the need for coronary bypass. **ExerDop** can be used to record pertinent data while the patient is either exercising or is at rest. It is a stand-alone system that can be used in conjunction with any stress measurement system. And, because it's noninvasive, **ExerDop** is extremely useful for serial studies of left ventricular performance.



Now accurate peak velocity and acceleration data can be obtained quickly, easily, and inexpensively—making **ExerDop** a valuable tool for cardiologists, laboratory researchers, and clinical diagnosticians. For more information, please contact:

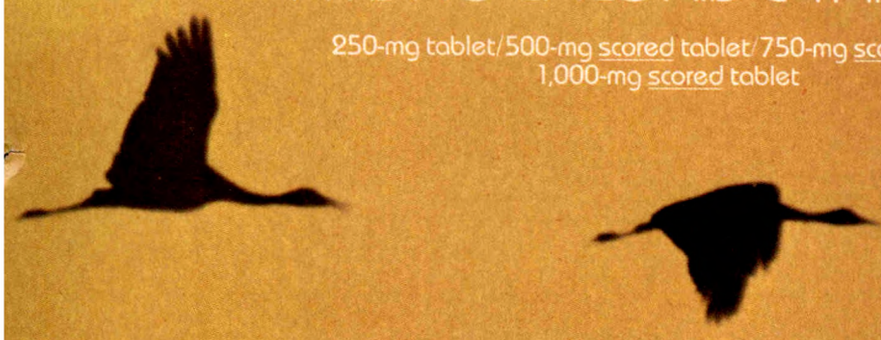
Return to a natural cardiac rhythm

SUSTAINED RELEASE

Procan® SR

(PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet/500-mg scored tablet/750-mg scored tablet
1,000-mg scored tablet



Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

- Administered half as often as conventional oral procainamide
- Wide versatility in cardiac conditions
- Can be used concomitantly with digoxin
- Ideal maintenance therapy

Procan SR... the original sustained-release oral procainamide

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

PROCAN® SR (procainamide hydrochloride tablets)
SUSTAINED RELEASE
Before prescribing, please see full prescribing information.
A Brief Summary follows.

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions, ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: Hypersensitivity to procainamide is an absolute contraindication. In this connection, cross-sensitivity to procaine and related drugs must be borne in mind.

Procainamide should not be administered to patients with complete atrioventricular heart block. It is also contraindicated in cases of second degree and third degree A-V nodal block unless an electrical pacemaker is operative.

It has been suggested that procainamide be contraindicated in patients with myasthenia gravis.

WARNINGS: Granulocytopenia may follow the use of procainamide, and deaths from sepsis have occurred. Leukocyte changes are most likely to occur during the first three months of therapy. During this time routine blood counts should be done at least every two weeks, and thereafter at longer intervals throughout maintenance procainamide therapy. Complaints of malaise and aches (a flu-type syndrome) are often reported in association with the granulocyte depression.

Patients should be instructed to report such symptoms promptly, as well as any soreness of mouth, throat or gums, unexplained fever, or symptoms of an upper respiratory tract infection. If these should occur and a complete blood count indicates a granulocyte depression, procainamide therapy should be discontinued immediately and appropriate treatment instituted. Recovery of leukocyte count usually occurs within a few weeks.

The incidence of granulocytopenia appears to be higher with procainamide sustained-release tablets than with standard tablets.

PRECAUTIONS: General—During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Serious hypotension can result from peripheral vasodilation and from decreases in cardiac output. At high plasma levels, procainamide may produce sinus tachycardia due to reflex sympathetic response to its hypotensive effect. Large doses may increase cardiac automaticity and can induce complete atrioventricular block, cardiac standstill, or ventricular extrasystoles that may proceed to ventricular fibrillation. These effects on the myocardium are reflected in the electrocardiogram: a widening of the QRS complex occurs most consistently; less regularly, the P-R and Q-T intervals are prolonged, and the QRS and T waves show some decrease in voltage.

Antinuclear antibodies (ANA) are often found in patients receiving long-term procainamide therapy. The induction of ANA appears to be independent of dosage. Patients with procainamide-induced increases in ANA titers may develop a syndrome resembling systemic lupus erythematosus (SLE). The mechanism of this syndrome is uncertain. Polyarthralgia, arthritic symptoms, and pleuritic pain are common symptoms; to a lesser extent fever, myalgia, skin lesions, pleural effusion, pericarditis, headache, fatigue, weakness, nausea and abdominal pain may occur. Rare cases of thrombocytopenia, Coombs' positive hemolytic anemia, increased SGOT, SGPT, and serum amylase have been reported which may be related to this SLE-like syndrome.

It is recommended that tests for systemic lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy. The drug should be discontinued if there is a rising ANA titer or clinical symptoms of SLE appear. The SLE-like syndrome may be reversible upon discontinuation of the drug. If discontinuation does not cause remission of the symptoms, corticosteroid therapy may be effective. If the SLE-like syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, corticosteroid suppressive therapy may be used concomitantly with procainamide.

Information for Patient—Practitioners should give the following information and instructions to patients receiving Procan SR.

1. Do not crush or chew these tablets. Swallow them whole.
2. Take this medicine exactly as directed by your doctor. Do not miss any doses and do not take more medicine than ordered. Do not stop taking this medicine without first checking with your doctor.
3. If you miss a dose and remember within one hour or so, take it as soon as possible. Then go back to your regular dosing schedule. Do not take double doses. If you have any questions about this, check with your doctor.
4. Report to your doctor any flu-type symptoms, such as malaise and aches, as well as any soreness of the mouth, throat or gums, unexplained fever, skin rash, unusual bleeding or bruising, symptoms that resemble arthritis, or symptoms of an upper respiratory tract infection.
5. Do not be concerned if you occasionally notice in your stool something that looks like a tablet. In Procan SR (procainamide hydrochloride tablets), the drug is 'held' in a wax core that has been specially designed to slowly release the drug for your body to absorb. When this process is completed the empty, nonabsorbable wax core, which looks nearly unchanged, is eliminated from your body.
6. Keep container tightly closed and store in a cool, dry place.

Laboratory Tests—Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals.

Routine blood counts are advisable during maintenance procainamide therapy. See WARNINGS for additional information.

Plasma concentrations of procainamide and NAPA should be monitored in patients with renal disease, hepatic disease, cardiac failure, or low cardiac output states.

Drug Interactions

1. **Antiarrhythmics:** Concurrent use with procainamide may result in additive cardiac effects and/or additive toxic effects.
2. **Anticholinergics:** Procainamide enhances the anticholinergic effects. Extreme caution must be exercised with such a combination.
3. **Anticholinesterases:** Procainamide antagonizes the effect of anticholinesterases in myasthenia gravis, and paralysis returns.
4. **Antihypertensives:** Procainamide may potentiate the hypotensive effects of thiazide diuretics and other antihypertensive agents. Adjustment of dosage may be required.
5. **Cimetidine:** It has been reported that the histamine H_2-antagonist cimetidine reduces renal clearance of procainamide and NAPA, resulting in higher plasma concentrations for longer durations. Caution should be exercised when administering these drugs concurrently, especially in the elderly, who have a reduced ability to clear all three. Dosage modification may be required.
6. **Neuromuscular Blocking Agents:** Procainamide potentiates the effects of skeletal muscle relaxants such as succinylcholine. It also may enhance or prolong the neuromuscular blocking activity of bacitracin, colistimethate, dihydrostreptomycin, gentamicin, gramicidin, kanamycin, neomycin, polymyxin B, streptomycin, and viomycin, producing respiratory depression.

Pregnancy—Pregnancy Category C. Animal reproduction studies have not been conducted with procainamide. It is also not known whether procainamide can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Procainamide should be given to a pregnant woman only if clearly needed.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when procainamide is administered to a nursing woman.

ADVERSE REACTIONS: Most frequent, especially with large oral doses:
1. Anorexia 2. Nausea 3. Vomiting 4. Diarrhea 5. Urticaria 6. Pruritus.

Less frequent: 1. Reactions in patients on long-term procainamide therapy: a. Antinuclear antibodies (ANA) b. Syndrome resembling systemic lupus erythematosus (SLE) (See PRECAUTIONS).

2. Hypersensitivity reactions: a. Angioneurotic edema b. Maculopapular rash c. Fever d. Eosinophilia e. Hypergammaglobulinemia.

Infrequent: 1. Granulocytopenia, sometimes resulting in death (See WARNINGS) 2. Convulsions 3. Psychosis with hallucinations 4. Confusion 5. Mental depression 6. Giddiness 7. Lightheadedness 8. Weakness 9. Bitter taste.

Rare: 1. Hypotension 2. A case was reported with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following a single dose of the drug.

OVERDOSAGE: Signs and symptoms of overdosage of procainamide include severe hypotension, ventricular fibrillation, widening of the QRS complex, junctional tachycardia, intraventricular conduction delay, oliguria, lethargy, confusion, nausea, and vomiting.

If ingestion is recent, gastric lavage or emesis may reduce absorption. Dopamine, phenylephrine or levarterenol may be helpful in reversing severe hypotensive responses.

Management of overdosage includes symptomatic treatment with ECG and blood pressure monitoring. Procainamide toxicity can usually be treated, if necessary, by administering vasopressors after adequate fluid volume replacement. Intravenous infusion of 1/6 molar sodium lactate injection reportedly reduces the cardiotoxic effects of procainamide.

The urinary elimination of procainamide is proportional to the glomerular filtration rate but is also affected by changes in urinary pH. Procainamide is relatively lipid-soluble as a free base, but the ionized form is not. Acid urine, therefore, leads to ion trapping of procainamide which enters the urine by passive diffusion from the plasma. Accordingly, renal clearance of procainamide can be considerably increased by maintaining a low urinary pH and high flow rates.

If procainamide toxicity causes severe hypotension and renal insufficiency, urinary elimination of procainamide and NAPA is decreased, and hemodialysis may be required. Hemodialysis significantly reduces the serum half-life of procainamide, and effectively removes procainamide and NAPA. Peritoneal dialysis is not effective.

It has been reported that one patient who ingested approximately 7 grams of procainamide hydrochloride recovered after treatment consisting of IV levarterenol, IV furosemide, attempted volume expansion with albumin, and hemodialysis. Also reported is the case of an elderly patient who recovered after ingestion of approximately 19 grams of procainamide hydrochloride. The patient was treated with IV isoproterenol and IV epinephrine. The latter report suggested that insertion of a ventricular pacing electrode is a reasonable precautionary measure in case high grade A-V block develops.

Storage Conditions—Protect from moisture. Store bottles below 30° C (86° F). Store unit-dose packages at controlled room temperature, 15°-30° C (59°-86° F). 0207G012
Caution: Federal law prohibits dispensing without prescription.

SYSTEMIC HYPERTENSION

Systolic Hypertension in the Elderly Program (SHEP): Antihypertensive Efficacy of Chlorthalidone

STEPHEN B. HULLEY, MD, MPH, CURT D. FURBERG, MD, BARRY GURLAND, MD, ROBERT McDONALD, MD, H. MITCHELL PERRY, MD, HAROLD W. SCHNAPER, MD, JAMES A. SCHOENBERGER, MD, W. McFATE SMITH, MD, MPH, and THOMAS M. VOGT, MD, MPH, *for the* SHEP Research Group

The Systolic Hypertension in the Elderly Program (SHEP) is a randomized, blinded test of the efficacy of antihypertensive drug treatment. In a large feasibility trial, 551 men and women who had isolated systolic hypertension and were at least 60 years old received chlorthalidone (25 to 50 mg/day) or matching placebo as the step I drug. After 1 year, 83% of the chlorthalidone group and 80% of the placebo group were still taking SHEP medications. Of those still taking chlorthalidone, 88% had reached goal blood pressure (BP) without requiring a step II drug, and most had responded to the lower dose (25 mg/day). The BP response was similar in all age, sex and race subgroups, with an overall mean difference between randomized groups of 17 mm Hg for systolic BP ($p < 0.001$) and 6 mm Hg for diastolic BP ($p < 0.001$). The only common adverse effects were asymptomatic changes in the serum levels of potassium (0.5 mEq/liter lower in the chlorthalidone group, $p < 0.001$), uric acid (0.9 mg/dl higher, $p < 0.001$) and creatinine (0.08 mg/dl higher, $p = 0.02$). This study indicates that chlorthalidone is effective for lowering BP in elderly patients with systolic hypertension and sets the stage for a larger trial of the effects of such treatment on the incidence of cardiovascular disease.

(Am J Cardiol 1985;56:913–920)

Manuscript received February 27, 1985; revised manuscript received June 4, 1985, accepted June 6, 1985.

Address for reprints: Stephen B. Hulley, MD, Building One, Room 201, San Francisco General Hospital, San Francisco, California 94110.

The 1984 report from the Joint National Committee on the Detection, Evaluation and Treatment of High Blood Pressure[1] provided a comprehensive set of policy guidelines on the management of diastolic hypertension. One important issue that remains unsettled, however, is whether to treat isolated systolic hypertension.[1–3] The prevalence of this condition, defined as a systolic blood pressure (BP) of 160 mm Hg or greater with a diastolic BP less than 90 mm Hg, increases to about 20% in both sexes by age 80 years[4–6]; 3 million persons in the U.S. are affected. The health implications of isolated systolic hypertension are similar to those for diastolic hypertension: a 2- to 3-fold excess risk of cardiovascular mortality.[5,7–10] Whether antihypertensive treatment with drugs will prevent some or

all of the excess cardiovascular events and whether such treatment is safe remain to be established.

The Systolic Hypertension in the Elderly Program (SHEP) is a large collaborative trial to resolve these uncertainties in a randomized design with a blinded placebo control. Findings pertaining to 3 of the topics studied during the 4-year feasibility study are presented: (1) the degree to which elderly patients comply with the antihypertensive treatment protocol, (2) the degree to which their systolic BP responds to drug therapy, and (3) the degree to which adverse effects are a problem.

Methods

Overall design: Elderly men and women who met eligibility criteria at 4 baseline examinations were randomized in a double-blind fashion to chlorthalidone or matching placebo. Those who did not respond adequately to 1 capsule daily of this step I drug (25 mg of chlorthalidone) progressed sequentially to 2 capsules daily and to step II drugs or placebo. The outcome variables were the compliance with the treatment protocol, the BP response and the adverse effects of medication.

Recruitment: The recruitment of study participants in the 5 clinical centers has been described in detail[11–14] and is summarized briefly herein. A total of 27,199 men and women aged 60 or older volunteered to have 3 BP measurements during screening examinations carried out in various community sites;[14] 16,629 (61%) reported that they were not receiving antihypertensive medication and 2,601 (16%) of these met the BP criteria for attending the first baseline clinic visit (systolic BP 160 to 239 mm Hg and diastolic BP less than 100 mm Hg). Of these 1,834 (71%) attended this first visit. A surprisingly large proportion of those screened (39%) reported current use of antihypertensive drugs; 1,899 of these were invited and 696 agreed to a carefully supervised withdrawal of medications. Of these, 308 became eligible for the first clinic visit and 125 were randomized.

Three baseline clinic visits were used to identify the participants who were subsequently randomized into the study. In addition to the BP criteria at each of these visits (systolic BP 150 to 239 mm Hg and diastolic BP less than 95 mm Hg at each of the first 2 clinic visits; systolic BP 160 to 219 mm Hg and diastolic BP less than 90 mm Hg at the third clinic visit), eligibility requirements included geographic stability and absence of the following: coronary bypass surgery within 2 years or heart attack within 6 months; stroke with residua; current treatment with antihypertensive drugs, insulin or anticoagulants; allergy to study medications; specified arrhythmias or a pacemaker; uncontrolled congestive heart failure; serum creatinine level of 2.0 mg/dl or more; alcohol abuse; cancer or other life-threatening disease; chronic obstructive pulmonary disease; peripheral vascular disease with tissue injury; senile dementia; residence in a nursing home; carotid bruit with history of transient ischemic attacks; and history of malignant hypertension. Of the 2,130 participants seen at the first clinic visit, 551 (26%) reached the third clinic visit and were randomized, 422 (20%) were eligible but refused participation, 967 (45%) failed BP criteria (almost always because systolic BP was not high enough), 116 (5%) failed other explicit eligibility criteria and 74 (4%) were excluded by clinical judgment. Overall yield from screening to randomization was 2%.

Hypothesis, sample size and randomization: The written a priori hypothesis stated that participants in the step I active drug treatment group would have a lower mean systolic BP than those in the step I placebo group after 1 year of follow-up. We specified an "intention to treat" rule (with study groups divided by the randomized assignment regardless of subsequent crossovers) and a plan for replacing any missing annual visit BP with the last available value. The designated sample size of 500 had a power of 0.90 to detect a mean difference in systolic BP of 6 mm Hg at a 1-tailed α of 0.05.

Each randomization was carried out by telephone between the clinic staff and the coordinating center data manager, who checked that eligibility criteria were met before assigning the participant to chlorthalidone or placebo. The ratio of assignment to these 2 groups was 4:1 to increase the number of participants who would receive an active step II drug and the power for contrasts among them. We used an adaptive randomization procedure that varied treatment assignment probabilities by 10% in one or the other direction in order to balance the step I study groups within race, sex, age and baseline systolic BP strata.[15]

Blood pressure treatment: Upon randomization into the study, participants entered the step-up protocol and received 25 mg/day of chlorthalidone or placebo (supplied as identical capsules by USV Pharmaceutical Corp.). Clinic visits were then scheduled at 4-week intervals unless the participants achieved goal BP (systolic BP less than 160 mmHg or 20 mm Hg below the baseline level, whichever was lower) for 2 consecutive visits, after which "maintenance" visits were scheduled at 8-week intervals. If BP had not reached goal after 4 weeks and if no adverse effects had occurred, the dosage was increased to 2 capsules of chlorthalidone or placebo daily. Twelve weeks after randomization, participants receiving chlorthalidone who had not reached goal BP were randomized to 1 of 4 step II drugs (reserpine, 0.05 mg twice daily; metoprolol, 50 mg twice daily; hydralazine, 25 mg twice daily; or matching placebo twice daily) (supplied by Ciba-Geigy). Participants receiving step I placebo who had not reached goal underwent a dummy randomization, and all received step II placebo twice daily. Twelve weeks later, the dosage for participants who still had not reached goal was doubled.

Participants on the maintenance schedule whose BP increased above goal for 2 consecutive visits were returned to the step-up schedule. Participants whose BP reached "escape" levels (that is, systolic BP of 220 mm Hg or higher or diastolic BP 100 mm Hg or higher at any visit) were seen at weekly intervals and stepped-care medications were advanced at an accelerated schedule until the BP fell below these levels or the participant reached step II, dose 2 and SHEP medications were discontinued in favor of open treatment with known drugs.

Outcome variables: *Blood pressure* was measured with a random 0 mercury manometer after participants had been sitting in a quiet room for 5 minutes. Systolic BP was defined as the first point at which sounds were recognizable, and diastolic BP as the point when sounds ceased to be heard. Two measurements were made at each visit by staff trained and certified in the procedures, and the mean was used to represent that visit. BP measurements were subjected to an extensive quality control program, including periodic recertification of the technicians, site visits by the quality control coordinator and periodic inspection of the data for low precision and digit preference.

Compliance with the SHEP treatment protocol was measured by capsule count, by self-report and by urine tests for the presence of chlorthalidone, using methods that have been described.[16] We also examined the rate at which SHEP medications were terminated in each of the study groups, and assessed the participants' adherence to the regular treatment visit schedule.

TABLE I Characteristics of the Randomized Cohort at Baseline by Study Group

	Study Group		
	Chlorthalidone (n = 443)*	Placebo (n = 108)*	Significance of Difference†
Demographics			
Aged >70 years	60%	65%	
Women	63%	64%	
Non-white	18%	20%	
Married	50%	47%

Weight, mean ± SD (lbs)	159 ± 32	158 ± 30	
Abnormal fundi	34%	26%	
Carotid bruit	5%	10%	p = 0.04

* Participants were randomized at step I in a ratio of 4:1 (chlorthalidone:placebo) to increase the number who would be available for subsequent randomization to step II active drugs. In this report only the results classified by step I randomization are reported.

† Nominal p values for the contrasts between study groups were computed by χ^2 test (Fisher's exact for contrasts with an expected n of 5 or less in any 1 cell) or a 2-tailed *t* test. No adjustment for multiple comparisons was made. The p values are given only for contrasts with $p < 0.10$.

BP = blood pressure; SD = standard deviation.

Symptoms that might represent adverse effects were assessed at every clinic visit by asking participants if they had felt unwell in any way since the prior clinic visit. At the baseline visit, the 1-month visit and the annual visit, the clinician also asked whether the participant had experienced any of 22 specified symptoms. (At the intervening visits only volunteered symptoms were recorded.) The severity of each symptom was characterized by the participant as "not troublesome," "troublesome" or "intolerable;" only the latter 2 responses are presented in this report.

Serum biochemistry levels were measured at specified intervals by Bio-Science Laboratories on a Technicon SRA-2000 multichannel analyzer using the hexokinase method for glucose, an ion-specific electrode for potassium, the uricase method for uric acid and the Jaffe reaction method (with picric acid) for creatinine; serum cholesterol levels were measured with an enzymatic method on a Cotas centrifugal analyzer. Clinicians used their judgement about prescribing potassium supplements (generally Bi-K™, 15 to 30 ml/day) to participants with low potassium levels, and allopurinol or probenecid to those with high uric acid levels. A system by which study group assignment could be discovered by local clinicians in the event of emergency was used on 3 occasions.

Data management: We developed a distributed system for data processing and telecommunications for the study.[17] This system used Wang minicomputers at each center to maximize compliance with the treatment protocol and to enhance the accuracy, timeliness and completeness of the data.

Results

Characteristics of the study cohort: Of the 551 participants in the SHEP study cohort, 443 were randomized to receive chlorthalidone as the step I drug and 108 to receive placebo. Mean values for systolic BP and diastolic BP in the chlorthalidone group at baseline were 172 and 75 mm Hg, respectively. These and other baseline variables were reasonably well distributed between the 2 randomized groups (Table I), although 2 variables (angina and carotid bruit) were more common in the placebo group at a nominal (unadjusted for multiple comparisons) 2-tailed $p < 0.05$.

Compliance: At the end of the year of observation, the vital status of all 551 participants was known. Among the 540 (98%) still alive, 93% of the chlorthalidone group and 97% of the placebo group attended the annual examination (Table II). The percentage permanently discontinuing step I SHEP drugs was 17% in the chlorthalidone group and 20% in the placebo group after 1 year of follow-up; two-thirds of these terminations occurred during the first 6 months.

Among those still taking medications at the annual visit, compliance with step I SHEP medications was assessed by counting the capsules returned at each visit, by asking the participants whether they had omitted any dosages of the SHEP medications and by

TABLE II Compliance with Step I SHEP Medications After 1 Year of Follow-Up by Study Group

	Chlorthalidone		Placebo	
	Overall Compliance in Those Alive at 1 Year*	Compliance in Those Prescribed SHEP Medications and with Complete Data†	Overall Compliance in Those Alive at 1 Year*	Compliance in Those Prescribed SHEP Medications and with Complete Data†
Attended anniversary visit	93%		97%	
SHEP medications still prescribed	83%		80%	
Capsule count reveals ≥ 80% of expected consumption since prior visit	71%	88%	69%	90%
Participants report taking all capsules in past week	76%	91%	71%	89%
Urine chlorthalidone present	72%	86%	. . .	. . .

* Vital status was established for all 551 participants, and the 540 (98%) who were alive after 1 year of follow-up are the denominator for the overall compliance columns.

† The denominator for these columns exclude the participants whose SHEP medications have been terminated and also those with incomplete compliance data (2% of the chlorthalidone and 3% of the placebo group for the capsule counts, none of either group for the self-reports and 4% of the chlorthalidone group for the urine tests).

SHEP = Systolic Hypertension in the Elderly Program.

chemically testing the urine for chlorthalidone. The results indicate that more than 85% of the participants in both study groups complied with their SHEP prescriptions.

Blood pressure response: Mean systolic BP in the chlorthalidone group decreased from 172 to 146 mm Hg during the first month of treatment, and there was a small further decline over the year of follow-up (Fig. 1). In the placebo group, mean systolic BP decreased to a lesser extent, leaving a net difference between the randomized groups that ranged from 10 to 13% during the year. (The early decline in the placebo group is attributed chiefly to regression to the mean.) Mean diastolic BP also fell during the first month of treatment (from 75 to 70 mm Hg) and the contrast between randomized groups ranged from 5 to 8% during the year.

The 17 mm Hg difference in mean systolic BP between randomized groups after 1 year of follow-up, the point in time specified in our 1-tailed intention-to-treat hypothesis, was highly significant ($p < 0.001$). Stratification revealed no major differences in the magnitude of BP response in various age, race and sex subgroups (Table III). An analysis that was not by intention to treat, i.e., restricted to participants who were taking SHEP medications at annual visit, also revealed a difference of 17 mm Hg for systolic BP and 6 mm Hg for diastolic BP.

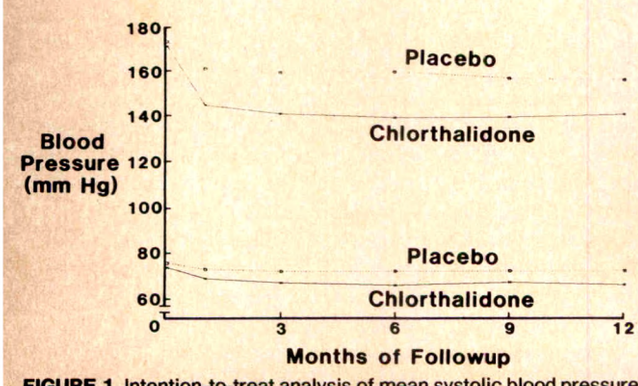

FIGURE 1. Intention-to-treat analysis of mean systolic blood pressure (BP) (**upper curves**) and diastolic BP (**lower curves**). Data represent the visit closest to the indicated time from randomization, within abutting windows of ± 1.5 months (± 0.5 for the 1-month data), and with adjustment for missing data as in Table III.

The distribution of individual BP responses at annual visit (Fig. 2) shows that the response to treatment was uniform. Among those still taking chlorthalidone at annual visit, 88% had not required a step II drug, and 56% were still at the lower (25-mg) dosage. In the placebo group, in contrast, 56% of participants taking SHEP medications at annual visit had advanced to step II (placebo) medication.

BP escape (systolic BP 220 mm Hg or higher or diastolic BP 100 mm Hg or higher) occurred in 4 (1%) participants assigned to chlorthalidone and 8 (7%) participants assigned to placebo. The BP returned to satisfactory levels in all, although 3 of the chlorthalidone and 4 of the placebo participants terminated their SHEP medications and began taking drugs prescribed by their personal physicians.

Symptoms: One month after beginning SHEP medications, the aggregate prevalence of reporting 1 or more troublesome or intolerable symptoms was similar to the baseline finding (about one-third in both study groups) and no symptom was significantly more common in the chlorthalidone group (Table IV). After 1 year of follow-up, the aggregate prevalence had increased somewhat, but remained comparable in the 2 study groups. An analysis restricted to those still taking SHEP medications also revealed no significant excess at 1 year in the chlorthalidone group. Problems in sexual function were reported by 6% of the men in the chlorthalidone

TABLE III Blood Pressure After One Year of Follow-Up by Age, Sex, Race and Study Group—Intention-to-Treat Analysis Adjusted for Missing Data

	No. of Participants*		Systolic BP (mm Hg)			Diastolic BP (mm Hg)		
	Chlorthalidone	Placebo	Chlorthalidone	Placebo	Difference	Chlorthalidone	Placebo	Difference
Age 60–69	176	38	140	159	19†	70	78	8*
70–79	200	56	142	158	16†	67	72	5*
80+	67	14	142	160	18†	63	70	7*
Women	279	70	142	158	16†	66	72	6*
Men	164	38	139	158	19†	69	76	7*
White	365	87	141	157	16†	68	74	6*
Non-white	78	21	142	165	23†	67	71	4
Overall	443	108	141	158	17†	68	74	6*

All statistics are computed by study group assignment, regardless of whether the participant continued to take SHEP medications.
* The measured BP was used for those attending the annual visit (n = 401 in chlorthalidone and n = 104 in placebo groups), and the closest preceding value was substituted for those who did not attend.
† $p < 0.01$ (1-tailed not adjusted for multiple comparisons).
BP = blood pressure; SHEP = Systolic Hypertension in the Elderly Program.

group and none of the men in the placebo group, but the contrast did not reach statistical significance.

Events that were believed possibly drug-related by the blinded SHEP clinicians contributed to the decision to terminate SHEP medications in 7 participants assigned to the chlorthalidone group (3 had dizziness on standing, 1 syncope on standing, 1 a rash, 1 hyperglycemia and 1 complained of problems in sexual function) and in 2 participants assigned to the placebo group (1 developed asthma and 1 had blood pressure escape).

Serum biochemistry levels: After 4 weeks of SHEP medications, mean potassium levels had fallen from 4.5 to 3.9 mEq/liter in the chlorthalidone group ($p < 0.001$) and remained unchanged (at 4.4 mEq/liter) in the placebo group. Levels below 3.5 mEq/liter occurred in 21% of the chlorthalidone group, and levels below 3.0 mEq/liter in 1%. By the annual visit clinicians had elected to prescribe potassium supplements to 13% of the chlorthalidone group and 4% of the placebo group (all of the latter had terminated SHEP medications and been given a diuretic drug by their personal physicians). The mean potassium level and prevalance of hypokalemia were similar to the 1-month values (Table V). Of the 16% with levels below 3.5 mEq/liter in the chlorthalidone group, 46% were at the 50-mg/day dosage. The distribution of individual responses is shown in Figure 3.

Serum creatinine level after 1 year of follow-up was slightly higher in the chlorthalidone group (1.10 vs 1.02 mg/dl, $p = 0.02$), and the proportion with a serum creatinine level 2.0 mg/dl or greater increased slightly in both groups (possibly owing to regression to the mean, because a level below 2.0 mg/dl was a requirement for entering the study). Only 1 person reached a level above 3.0 mg/dl; this patient, whose level was 4.5 mg/dl, was in the chlorthalidone group.

Serum uric acid level was substantially higher in the chlorthalidone group at annual visit (6.8 vs 5.9 mg/dl, $p < 0.001$), but acute gout developed in only 1 chlorthalidone-treated person. Serum cholesterol levels were not significantly altered by the treatment assignment. The nonfasting serum glucose level was slightly higher in the chlorthalidone group ($p = 0.09$), and there was 1 instance of glucose intolerance that required treatment.

Discussion

We conclude that chlorthalidone treatment of elderly patients with isolated systolic hypertension is acceptable to most and produces a substantial lowering of BP. These conclusions from our randomized double-blind study are compatible with the similar findings of the European Working Party High Blood Pressure in the Elderly Trial,[18] the results of nonrandomized studies

Mean ± SD	5.7 ± 1.2	5.6 ± 1.3	6.8 ± 1.5	5.9 ± 1.4	<0.001
Serum glucose (mg/dl)					
Mean ± SD	110 ± 35	108 ± 33	111 ± 40	104 ± 28	0.09
Serum cholesterol (mg/dl)					
Mean ± SD	238 ± 42	242 ± 39	238 ± 46	243 ± 41	

* The number of observations (slightly smaller at 1 year than the number attending clinic because of 5 missing sera) are for all biochemistry values except cholesterol, for which the number at baseline was 439 and 108, and at 1 year 385 and 98, in the chlorthalidone and placebo groups, respectively.

Statistical significance of the contrasts between study groups was computed as in Table I, and is shown in the table if nominal 2-tailed $p < 0.10$; none of the contrasts at baseline reached this level of significance.

SD = standard deviation.

of isolated systolic hypertension treatment in the elderly[19,20] and the results of randomized but non-double-blind trials of diastolic hypertension treatment in the elderly.[21,22]

Although the level of compliance in our study was high, it is difficult to estimate how this would translate to ordinary treatment in the general population. Our choice of relatively healthy and well-motivated volunteers may have enhanced the degree of compliance. However, some instances of discontinuation of SHEP medications may have been a result of participants' concerns about the possibility that they were receiving a placebo.

An unanticipated finding was the efficacy of chlorthalidone as a sole drug for lowering BP; among those still receiving SHEP medications at the annual visit, 88% had reached goal without recourse to step II drugs, and usually required only 25 mg/day. Even lower doses may be effective, and we will be reporting on dosage reduction to a level of 12.5 mg/day of chlorthalidone in a study carried out during the second and third years of follow-up.

A common biochemical effect of chlorthalidone was hypokalemia, with potassium levels below 3.5 mEq/liter in about one-fifth of the chlorthalidone-treated group. SHEP clinicians elected potassium supplementation for many of these participants. Potassium levels below 3.0 mEq/liter were rare, however, and the clinical importance of the moderate chlorthalidone-induced potassium depletion observed in this and other studies of diuretic drugs[23–25] is uncertain. Some studies[24,26] of diuretic treatment show an increase in the rate of ventricular premature complexes and other arrhythmias, while others[27,28] have not; in either event, the evidence that this may be linked to sudden death or other serious clinical events remains uncertain,[29,30] controversial,[31] and limited to younger age groups than the population reported here.

Another biochemical effect of chlorthalidone was a substantial increase in mean serum uric acid levels. This is a well-known metabolic consequence of diuretic treatment,[18,21] which occasionally causes acute gout (1 such case was observed here) but otherwise has no known clinical implication. A third biochemical effect was a small (0.08 mg/dl) increase in mean serum creatinine level in the group receiving chlorthalidone. A change of similar magnitude, of uncertain clinical importance, has been observed previously.[18,21] We did not observe the small increase in serum cholesterol level that has been noted in other populations.[23,32]

Although our study did not detect an excessive rate of symptoms or morbid events in the chlorthalidone group, this does not establish that the treatment is safe. This study was too small to reveal either a beneficial or an adverse effect of treatment on disease events during the first year of follow-up. We will be reporting on the disease event trends observed in this feasibility study when the 3-year follow-up period is completed. The results from the SHEP main trial will be available in about 5 years.

In the meantime, the inference that the increased risk of coronary heart disease and stroke in patients with isolated systolic hypertension can be reduced by treatment is supported by analogy with the beneficial response in clinical trials of treating diastolic hypertension in populations up to age 70 years[21,22], and older.[33] However, serious adverse effects are possible under some circumstances.[30,34] The advisability of drug treatment for isolated systolic hypertension in elderly populations remains uncertain.[1]

Acknowledgment: The SHEP investigators are grateful to Cary Fox, Kjeld Molvig and Sarah Harvey for the thoughtful care they gave the acquisition and analysis of the data, and to Christine Choy for her tireless support in the preparation of the manuscript.

Doppler Evaluation of Left Ventricular Diastolic Filling in Children with Systemic Hypertension

A. REBECCA SNIDER, MD, SAMUEL S. GIDDING, MD, ALBERT P. ROCCHINI, MD, AMNON ROSENTHAL, MD, MACDONALD DICK II, MD, DENNIS C. CROWLEY, MD, and JANE PETERS

To assess left ventricular (LV) diastolic function in children with systemic hypertension, 11 patients with hypertension (mean blood pressure 99 mm Hg) and 7 normal patients (mean blood pressure 78 mm Hg) underwent M-mode echocardiography and pulsed Doppler examination of the LV inflow. From a digitized trace of the LV endocardium and a simultaneous phonocardiogram, echocardiographic diastolic time intervals, peak rate of increase in LV dimension (dD/dt), and dD/dt normalized for LV end-diastolic dimension (dD/dt/D) were measured. Doppler diastolic time intervals, peak velocities at rapid filling (E velocity) and atrial contraction (A velocity), and the ratio of E and A velocities were measured. The following areas under the Doppler curve and their percent of the total area were determined: first 33% of diastole (0.33 area), first 50% of diastole, triangle under the A velocity (A area), and the triangle under the E velocity (E area). The A velocity (patients with hypertension = 0.68 ± 0.11 m/s, normal subjects = 0.49 ± 0.08 m/s), the 0.33 area/total area (patients with hypertension = 0.49 ± 0.09, normal subjects = 0.58 ± 0.08), the A area (patients with hypertension = 0.17 ± 0.05, normal subjects = 0.12 ± 0.03), and the A area/total area (patients with hypertension = 0.30 ± 0.11, normal subjects = 0.20 ± 0.07) were significantly different between groups ($p < 0.05$). M-mode and Doppler time intervals, (dD/dt)/D, E velocity, and the remaining Doppler areas were not significantly different between groups. The normal subjects and patients with hypertension did not differ significantly in echocardiographic LV size and thickness or in percent shortening fraction. This study shows that abnormal patterns of LV diastolic filling occur in children with mild systemic hypertension. These diastolic abnormalities are detectable by mitral valve Doppler ultrasound examination when standard M-mode echocardiographic indexes of diastolic function are still normal and before the development of systolic function abnormalities or LV hypertrophy on the M-mode echocardiogram.

(Am J Cardiol 1985;56:921–926)

Several recent echocardiographic and radionuclide studies have demonstrated left ventricular (LV) diastolic filling abnormalities in patients with a variety of cardiac diseases, including coronary artery disease, hypertrophic cardiomyopathy and systemic hypertension.[1–13] With the use of noninvasive indexes of LV relaxation and filling, these studies have shown that diastolic dysfunction often precedes systolic dysfunction and is often detectable in asymptomatic patients.[2,4,14] Some investigators have suggested that diastolic abnormalities are a characteristic finding in adult patients with early hypertensive heart disease.[4,6,10,12]

In this study we assessed LV diastolic function in a group of children with mild systemic hypertension using the noninvasive techniques of M-mode and Doppler echocardiography, identified the most sensitive Doppler indexes of LV relaxation, and compared the M-mode and Doppler techniques in their ability to detect early abnormalities of diastolic compliance.

Methods

Patients: The patient group included 11 children with systemic hypertension and 7 normal children. The normal group consisted of 3 girls and 4 boys who had no evidence of heart disease on physical examination or on M-mode and 2-dimensional echocardiography. They were 10 to 18 years old (mean 15) and weighed 41 to 73 kg (mean 64). The systolic blood pressure of the normal group at the time of the echocardiographic studies was 111 ± 8 mm Hg (mean ± standard deviation); the diastolic blood pressure was 62 ± 8 mm Hg.

The systemic hypertension group consisted of 6 girls and 5 boys who were randomly selected from the outpatient hypertension clinic. They were 1.4 to 17 years (mean 11) and weighed 8.9 to 75 kg (mean 42). The systolic blood pressure of the hypertension group at the time of the echocardiographic studies was 131 ± 13 mm Hg; the diastolic blood pressure was 82 ± 14 mm Hg. In the hypertension group, 7 children had essential hypertension, and 1 each had William's syndrome, primary aldosteronism, previous repair of coarctation of the aorta and atrophic pyelonephritis. The time interval from the

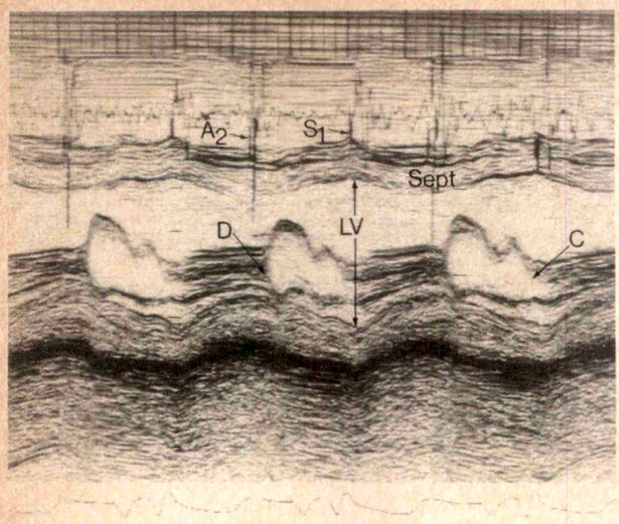

FIGURE 1. M-mode echocardiogram of the left ventricle (LV) with simultaneous phonocardiogram and electrocardiogram. Aortic valve closure (A_2) is the first high-frequency component of the second heart sound. first recorded elevation of the blood pressure to the echocardiographic study ranged from 1 day to 12 years; mean duration of known hypertension was 2.4 years. At the time of the echocardiographic study, 5 patients with hypertension were receiving no medications, 5 were taking diuretic drugs, 3 were receiving β-blocking drugs, 1 was taking captopril and 1 was taking hydralazine.

Echocardiographic examination: Each patient underwent an M-mode echocardiographic examination with a simultaneous phonocardiogram and a pulsed Doppler examination of the LV inflow. M-mode echocardiograms of the left ventricle were generated from the 2-dimensional sector scanner (Advanced Technology Laboratories Mark 600, 3-MHz transducer) using a cursor line positioned at the free edges of the mitral valve leaflets in the parasternal short-axis view (Fig. 1). An unfiltered phonocardiogram was obtained from the second left intercostal space and was recorded simultaneously with the M-mode echocardiogram and an electrocardiogram at a paper speed of 50 mm/s. A record was considered adequate for analysis only when the septal and posterior wall echoes and the time point D of mitral leaflet separation could be clearly identified for at least 3 entire cardiac cycles. Using a hand-controlled pen and a microprocessor system (Digisonics), the echocardiograms were digitized by tracing the endocardial echoes of the septum and the posterior wall.[15–17] From the digitized tracings, a computer printout of the absolute values of the LV minor axis dimension and the rate of change of this dimension with respect to time was available at 3-ms intervals.

From the M-mode echocardiograms, the septum, LV posterior wall and LV dimension were measured at end-diastole at the onset of the QRS wave.[18] LV dimension at end-systole was measured as the smallest systolic dimension from the digitized recording. The shortening fraction, the peak rate of increase in dimension (dD/dt), and the peak rate of increase in dimension normalized for LV end-diastolic dimension (dD/dt/D) were recorded. The normalization of the lengthening velocity, achieved by dividing the peak dD/dt by the LV end-diastolic dimension, allowed comparison of lengthening velocities between different-sized ventricles.[17] The following time intervals were measured from either the original M-mode echocardiogram or the digitized tracings[3,17]:

1. The cardiac cycle length was measured as the time interval between the peaks of 2 successive R waves on the electrocardiogram.
2. The isovolumic relaxation time was measured from the first high-frequency deflection of the aortic closure sound to the initial separation or D point of the mitral valve leaflets.
3. Protodiastole was measured from the point when −dD/dt reaches 0 (the minimum LV systolic dimension) to the aortic closure sound.
4. The total relaxation time was measured from the minimal LV systolic dimension to the point when dD/dt decreases to 50% of its peak value. This latter point corresponds roughly to the transition between the rapid filling and slow filling phases of diastole.[3,17]
5. The relaxation time was defined as the time from the minimal LV systolic dimension to peak dD/dt.
6. The rapid filling period was calculated as total relaxation time minus (isovolumic relaxation time + protodiastole).

Doppler examination: Immediately after M-mode examination, each patient underwent a range-gated pulsed Doppler examination of the LV inflow tract. Using the apical 4-chamber view, the Doppler cursor line and sample volume were placed in the mitral valve funnel at an angle as nearly parallel to flow as possible (Fig. 2). The sample volume position was adjusted so as to record the maximal velocity through the mitral valve. This point was usually found at the level of

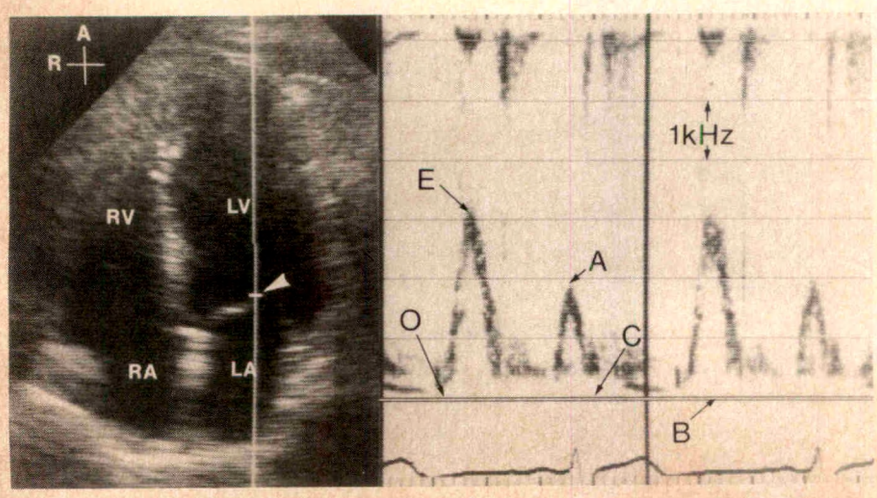

FIGURE 2. Pulsed Doppler spectral recording from the left ventricular inflow. The freeze-frame image of the apical 4-chamber view (**left**) shows the position of the sample volume (**white arrow**) on the Doppler cursor line at the time of the recording. The mitral valve Doppler spectral tracing (**right**) shows forward flow toward the transducer and above the baseline (B) during rapid ventricular filling (E) and atrial contraction (A). C = time point of mitral valve closure; LA = left atrium; LV = left ventricle; 0 = time point of mitral valve opening; RA = right atrium; RV = right ventricle. Orientation: A = anterior, R = right.

the mitral anulus.[19,20] All Doppler examinations were recorded with a 3.0-MHz transducer and a paper speed of 50 mm/s. The Doppler waveform was displayed with frequency shift on the vertical axis, time on the horizontal axis, and amplitude of the signal as shades of gray. Signals from blood flowing toward the transducer were displayed above the baseline and signals from blood flowing away from the transducer were displayed below the baseline. A Doppler examination was considered adequate for analysis only when the opening and closure points (0 and C points) of the mitral valve and the peak velocities at rapid ventricular filling (E point) and during atrial contraction (A point) could be identified for at least 3 cardiac cycles. The following Doppler time intervals were measured: the R to R interval, the time between the 0 to C points, 0 to E points, 0 to A points, the time between the 0 point and the point where the velocity decreases to 50% of its peak E value (which would be expected to correspond to the rapid filling period), the pressure half-time,[21] and the time between the 0 point and the point where the velocity decreases to the value of peak E/1.4. This latter point (where the velocity decreased to peak E/1.4) represents the time at which the LV diastolic pressure decreases to one-half of its peak value during rapid ventricular filling.[21] The interval between the 0 point and peak E/1.4 was included as another technique for measuring the rapid filling period. Also, from the Doppler spectral tracing, the peak E velocity, the peak A velocity, and the ratio of the peak E and peak A velocities were determined.

Because of the changes in the mitral valve cross-sectional area that occur throughout diastole, determination of the absolute volumetric flow in the different portions of diastole would be extremely difficult. Therefore, the Doppler patterns of LV filling were examined by integrating several areas under the Doppler spectral tracing (Fig. 3). The measured areas included the total area under the curve in diastole or the velocity time integral, the area under the curve for the first 50% of diastole, and the area under the curve for the first 33% of diastole (0.33 area). The E area and the A area were measured as the triangular portion under the Doppler curve formed by extrapolating a straight line down from the peak E and peak A velocities to the baseline. To determine the percent of the total velocity time integral occupied by the individual areas and to normalize the data for differences in preload and diastolic cycle lengths among the patients, each individual area was divided by the total area to obtain the area fractions:

$$\text{Area fraction} = \frac{\text{individual Doppler area}}{\text{total Doppler area}}$$

All Doppler areas were measured using a hand-controlled crosswire cursor and a microprocessor system (Microsonics CAD 888) with a spatial resolution of 0.1 mm. The recordings were traced along the densest portion of the Doppler curve and were extrapolated through the area of the wall filter setting to the baseline.

Data analysis: All M-mode and Doppler measurements reported are the average of 3 or more cardiac cycles. Statistical comparisons between the normal group and the hypertension group were made using an unpaired t test. A 2-tailed p value <0.05 was used to indicate a significant difference between groups. All values are reported as mean ± standard deviation. The relation between 2 variables was assessed by linear regression analysis; $p < 0.05$ was considered a significant correlation.

The beat-to-beat variation coefficients for selected diastolic measurements were calculated from 3 successive cardiac cycles of 6 studies (3 normal subjects and 3 patients with hypertension). The variation coefficients were: isovolumic relaxation time, 8.8%; (dD/dt)/D, 6.5%; the total area under the Doppler curve, 2.4%; the Doppler 0.33 area, 4.9%; the A area, 3.8%, the peak A velocity, 4.2%. To determine the interobserver variability, 6 records (3 normal subjects and 3 patients with hypertension) were analyzed independently by 2 observers. The mean percent error between the 2 observers [(first observer − second observer)/average of both observers] × 100, was as follows for selected diastolic measurements: isovolumic relaxation time, 9.8%; (dD/dt)/D, 4.9%; the total area under the Doppler curve, 2.8%; the Doppler 0.33 area, 2.4%; the A area, 3.8%; and the peak A velocity, 2.1%.

TABLE I Blood Pressure and Left Ventricular Measurements in Normal Subjects and Patients with Hypertension

Measurement	Normal Subjects	Patients with Hypertension	p Value
Systolic BP (mm Hg)	111 ± 8	131 ± 13	0.004*
Diastolic BP (mm Hg)	62 ± 8	82 ± 14	0.006*
LVDD (cm)	5.11 ± 0.45	4.36 ± 1.02	0.09
LVSD (cm)	3.04 ± 0.43	2.52 ± 0.65	0.08
SF	0.41 ± 0.06	0.42 ± 0.05	0.55
LVPW (cm)	0.81 ± 0.16	0.79 ± 0.19	0.77
Septum (cm)	0.77 ± 0.13	0.76 ± 0.20	0.89

* Statistically different between groups at the 5% level.
Values are mean ± standard deviation.
BP = blood pressure; LVDD = left ventricular end-diastolic dimension; LVPW = left ventricular posterior wall thickness; LVSD = left ventricular end-systolic dimension; SF = shortening fraction.

Results

A significant difference was found in the systolic and diastolic blood pressures between the 2 groups

interval by the cycle length did not change these results.[10] The peak A velocity of the systemic hypertension group was significantly higher than that of the normal subjects ($p = 0.002$).

With regard to the mitral valve area measurements (Table IV), the percent of the total area in the first third of diastole was significantly lower in the systemic hypertension group ($p = 0.04$). The A area and the percent of the total area under the A wave were significantly higher in the patients with hypertension ($p = 0.02$ and 0.05, respectively). With regard to M-mode and Doppler measurements, the only measurements that separated patients with systemic hypertension from normal subjects were the Doppler A-wave velocity, the Doppler A area, and the percent of the Doppler total area in the first one-third of diastole and under the A wave (Fig. 4). To determine if any of these 4 variables correlated with the severity of the hypertension, linear regression analysis was performed on the data pooled from both patient groups. There was no significant correlation between these 4 variables and systolic blood pressure, diastolic blood pressure, LV posterior wall thickness or septal thickness. Also, in the patients with hypertension, there was no correlation between the blood pressure and LV thickness.

Discussion

In adult patients with chronic hypertension, M-mode echocardiographic studies have shown diminished early peak LV diastolic filling rates, prolonged isovolumic relaxation time and shortened rapid filling period.[2,11,12,14] Similarly, radionuclide studies in adult patients with hypertension have revealed decreased early peak diastolic filling rates and decreased percent LV filling in the first one-third of diastole.[10,11] This study shows that abnormal patterns of LV diastolic filling occur in children with mild systemic hypertension and that these diastolic filling abnormalities are detectable by mitral valve Doppler examination when standard M-mode indexes of diastolic function are still normal and before the development of systolic function abnormalities or LV hypertrophy on the M-mode echocardiogram.

The decrease in the percent of the total area in the first one-third of diastole and the increase in the percent of the total area under the A wave in the children with hypertension suggest a relative shift of LV filling to late

diastole.[2,10] The impaired LV filling in early diastole was accompanied by a compensatory increase in LV filling in late diastole (during atrial contraction) so that the LV end-diastolic dimension and total area under the Doppler curve of the hypertension group were normal.

M-mode versus Doppler findings: In this study, abnormalities of diastolic filling were more easily recognized by mitral valve Doppler examination than by M-mode echocardiographic techniques. Several explanations are possible for this difference. First, even though the M-mode echocardiograms were obtained while imaging the LV minor axis, slight variations in the level of the cross-sectional plane from which the echocardiogram is obtained greatly influence measurements of the diastolic relaxation times and filling rates.[17,22] Second, the M-mode measurements vary considerably from beat to beat and with different observers. Despite this variability, the echocardiographic relaxation times and filling rates of our normal patients were similar to values reported by others.[3,17] Third, Bahler et al[17] showed that the time course of diastolic relaxation is dependent on cardiac cycle length; however, the velocity of relaxation is independent of cycle length. This factor may explain why diastolic filling abnormalities were more easily detectable with the Doppler indexes (which are velocity measurements) than with echocardiographic relaxation time indexes. Bahler reported that the isovolumic relaxation time is the time interval that is most independent of cycle length.[17] In our study, the isovolumic relaxation time was the only echocardiographic measurement that came close to being significantly different between the 2 groups. This finding further suggests that the remaining echocardiographic time indexes were influenced by heart rate and, therefore, were not useful in differentiating normal subjects from patients with hypertension.

There was far less beat-to-beat and interobserver variability in the mitral valve Doppler measurements. We have found that good-quality Doppler recordings suitable for analysis are easier to obtain than good-quality M-mode recordings suitable for digitizing. This is particularly true in adult patients in whom conditions such as obesity and chronic lung disease may make parasternal echocardiographic examination extremely difficult.

Factors affecting diastolic relaxation indexes: Diastolic indexes of LV relaxation can be influenced by several factors including heart rate and LV loading conditions.[23–25] Bahler et al[17] showed that the rapid filling phase occupies an increasing proportion of diastole as heart rate increases. Studies in the intact heart have shown that the duration of relaxation and the velocity of lengthening are intimately related to the velocity of shortening and the inotropic state.[26–30] In this study, differences in the diastolic filling patterns between the normal and the hypertension group cannot be explained on the basis of differences in heart rate, systolic function or LV loading conditions. The heart rates of the 2 groups were not different, either at the time of the M-mode examination or at the time of the Doppler examination. The systolic function of the 2 groups, as assessed by the M-mode shortening fraction, was normal. The LV end-diastolic dimensions of both patient groups were statistically similar, indicating no intergroup differences in ventricular loading conditions. Also, division of the individual Doppler areas by the total area under the Doppler curve and division of dD/dt by the LV end-diastolic dimension normalized these measurements for differences in preload.

Possible mechanisms and clinical implications of diastolic filling abnormalities: The abnormal diastolic filling noted in patients with systemic hypertension could be a result of (1) increased LV chamber stiffness caused by LV hypertrophy with normal myocardial stiffness or (2) decreased LV compliance caused by myocardial dysfunction or fibrosis.[10,25,31] The patients with hypertension in our study showed diastolic filling abnormalities in the presence of normal septal and posterior wall thicknesses. Possible explanations for this finding are that (1) diastolic abnormalities occur early in the course of systemic hypertension, even preceding development of LV hypertrophy, (2) total LV mass may be increased in patients with hypertension even when M-mode measurements show normal wall thickness,[13] or (3) hypertrophy may have already regressed in the patients receiving therapy.

Six patients with hypertension who were receiving antihypertensive therapy at the time of the echo-Doppler study and whose hypertension was under good control still had Doppler diastolic filling abnormalities. Using radionuclide techniques, Inouye et al[13] showed failure of reversal of LV diastolic filling abnormalities in patients with hypertension after therapy with diuretic, β-blocking and calcium channel-blocking drugs. These studies suggest that there may be irreversible changes in diastolic filling patterns that occur early in patients with systemic hypertension.[13,32,33]

Comparison of Doppler, echocardiographic and radionuclide indexes of left ventricular filling: Our values for the Doppler area fractions are very similar to Hanrath's values for percent dimensional increase measured from the echocardiogram and Inouye's values for first-third filling fraction measured from radionuclide techniques.[2,10] Hanrath et al[2] noted in normal subjects that 62 ± 10% of the total change in diastolic dimension occurred during the rapid filling phase of diastole and 16 ± 10% of the total dimensional change occurred during atrial contraction (compared with Doppler area fractions in our normal group of 0.58 ± 0.08 for 0.33 area/total area and 0.20 ± 0.07 for A area/total area). In Hanrath's patients with hypertension, 51 ± 12% of the total dimensional increase occurred during rapid filling and 23 ± 10% of the total dimensional increase occurred during atrial contraction (compared with Doppler area fractions in our hypertension group of 0.49 ± 0.09 for 0.33 area/total area and 0.30 ± 0.11 for A area/total area). Likewise, Inouye et al[10] showed a first-third filling fraction (counts in the first one-third of diastole divided by the total stroke count) of 0.60 ± 0.07 for normal subjects and 0.41 ± 0.13 for hypertensive patients age-matched to control subjects (compared with 0.33 area/total area of 0.58 ± 0.08 for normal subjects and 0.49 ± 0.09 for hypertensive patients).

These studies, using 3 different imaging and measurement techniques, all demonstrate a shift in the LV filling pattern to the latter part of diastole in patients with hypertension.

In conclusion, abnormalities of diastolic filling occur early in children with systemic hypertension, before M-mode evidence of LV hyertrophy and before clinical or echocardiographic evidence of systolic dysfunction. Measurement of diastolic filling patterns from the mitral valve Doppler examination appears to be a useful method of detecting early abnormalities of diastolic function. For assessing diastolic function, the Doppler area measurements appear to have less variability than the echocardiographic diastolic time intervals and filling rates and may allow earlier detection of diastolic filling abnormalities. The Doppler technique should be useful in assessing diastolic function in a wide variety of clinical situations, including the patients with coronary artery disease, myocarditis or cardiomyopathy, LV outflow tract obstruction and previous cardiac transplantation.

THERE'S MORE THAN ONE WAY TO PHASE AN ARRAY

Now you can have more detailed depiction of cardiac anatomy…better tissue differentiation…improved visualization of septal borders and blood-filled chambers…intricate detail of valve leaflets…in images from the ULTRAMARK®8 Ultrasound System. Because we've created the ultimate phased array for cardiac imaging.

ATL's exclusive *annular phased array* with a small footprint scanhead incorporates the most desirable characteristics of both mechanical and traditional phased array technology while overcoming their limitations. It electronically phases and focuses a unique transducer with 5 concentric rings to produce the thinnest tomographic slice in imaging with unparalleled axial and lateral resolution.

The result: higher resolution images dynamically focused in two dimensions for visualization of structural detail in cardiac anatomy as you've never seen it before.

But don't take our word for it—see for yourself.

Call today to arrange for a demonstration—800-982-2011; in Washington, call collect: (206) 487-7067.

NEW CLINICAL INDICATION:
M.I. PROPHYLAXIS IN TWO TYPES OF
AT-RISK CARDIOVASCULAR PATIENTS

AT-RISK PATIENT TYPE #1: THOSE WITH UNSTABLE ANGINA

One Alka-Seltzer® tablet a day reduced incidence of M.I. in patients with unstable angina by 51%

The Lewis/VA Cooperative Study[7]

Protocol: A multicenter, double-blind, randomized, placebo-controlled trial was conducted to determine the effects of daily soluble aspirin therapy on patients with unstable angina. 1,266 men in 12 VA medical centers were followed for 12 weeks. Inclusion criteria: chest pain suggestive of unstable angina beginning the previous month and still present; evidence of coronary-artery disease; and absence of baseline evidence of acute M.I. Patients randomly received either one tablet of Alka-Seltzer® dissolved in water daily for 12 weeks or buffered powder alone (placebo) dissolved in water and taken daily for 12 weeks. End point was either acute M.I. or death.

Results: The incidence of both nonfatal M.I. and mortality was 51% lower in the Alka-Seltzer® (buffered aspirin in solution) treated group.

Conclusion: "...aspirin has a protective effect against acute myocardial infarction in men with unstable angina, and...a similar effect on mortality."[7]

Further, "Because of the effectiveness and safety of the therapy, we recommend aspirin as used in this trial as a valuable addition to the management of unstable angina in men...who do not have contraindications to this drug."[7]

The primary reason for the selection of Alka-Seltzer® for this study was that "... no gastrointestinal blood loss was associated with this form."[7]

There was no significant difference in the incidence of self-reported side effects between the Alka-Seltzer® group and the placebo group.

The Aspirin Solution.

And to reduce reinfarction, see next page...

Alka-Seltzer® can also reduce mortality or reinfarction by 20%[9,10]

The Studies: Six separate clinical trials were conducted[1-6] to assess the efficacy of aspirin for reduction of incidence of mortality and reinfarction in patients with prior M.I. All six trials were randomized and placebo-controlled. Together, they evaluated 10,703 post-M.I. patients.

The Analysis: The six clinical studies were reviewed and analyzed by two teams of independent investigators.[9,10]

The Results: The combined results from the six clinical trials indicate that daily ingestion of aspirin reduced the incidence of reinfarction and/or death.

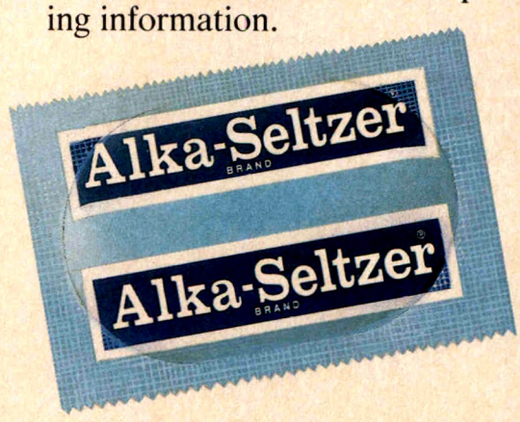
The Aspirin Solution.

No Gastric Bleeding

Because the aspirin in Alka-Seltzer® is ionized and in complete solution when you take it, there are no particles to come in contact with the gastric mucosa and cause gastric bleeding.[11,12]

Alka-Seltzer,® the aspirin solution, is the most highly buffered of all aspirin preparations.[13] As with all aspirin products, Alka-Seltzer® is contraindicated in patients with aspirin sensitivity, with asthma, or with coagulation disease. For sodium content, see full prescribing information.



©1985 Miles Laboratories, Inc., Elkhart, IN 46515

Alka-Seltzer®
Each tablet contains: aspirin 324 mg., heat treated sodium bicarbonate 1916 mg., citric acid 1000 mg. ALKA-SELTZER® in water contains principally the antacid sodium citrate and the analgesic sodium acetylsalicylate. Buffered pH is between 6 and 7.

Indication:
Aspirin is indicated to reduce the risk of death and/or non-fatal myocardial infarction in patients with a previous infarction or unstable angina pectoris.

Clinical Trials:
The indication is supported by the results of six, large, randomized multicenter, placebo-controlled studies[1-7] involving 10,816, predominantly male, post-myocardial infarction (MI) patients and one randomized placebo-controlled study of 1,266 men with unstable angina. Therapy with aspirin was begun at intervals after the onset of acute MI varying from less than 3 days to more than 5 years and continued for periods of from less than one year to four years. In the unstable angina study, treatment was started within 1 month after the onset of unstable angina and continued for 12 weeks and complicating conditions such as congestive heart failure were not included in the study.

Aspirin therapy in MI patients was associated with about a 20 percent reduction in the risk of subsequent death and/or non-fatal reinfarction, a median absolute decrease of 3 percent from the 12 to 22 percent event rates in the placebo groups. In aspirin-treated unstable angina patients the reduction in risk was about 50 percent, a reduction in event rate of 5 percent from the 10 percent rate in the placebo group over the 12 weeks of the study.

Daily dosage of aspirin in the post-myocardial infarction studies was 300 mg in one study and 900 to 1500 mg in five studies. A dose of 325 mg was used in the study of unstable angina.

Adverse Reactions:
Gastrointestinal Reactions: Doses of 1000 mg per day of aspirin caused gastrointestinal symptoms and bleeding that in some cases were clinically significant. In the largest post-infarction study (the Aspirin Myocardial Infarction Study (AMIS) with 4,500 people), the percentage incidences of gastrointestinal symptoms for the aspirin (1000 mg of a standard, solid-tablet formulation) and placebo-treated subjects, respectively, were: stomach pain (14.5%; 4.4%); heartburn (11.9%; 4.8%); nausea and/or vomiting (7.6%; 2.1%); hospitalization for gastrointestinal disorder (4.9%; 3.5%). In the AMIS and other trials, aspirin treated patients had increased rates of gross gastrointestinal bleeding. Symptoms and signs of gastrointestinal irritation were not significantly increased in subjects treated for unstable angina with buffered aspirin in solution.

Cardiovascular and Biochemical:
In the AMIS trial, the dosage of 1000 mg per day of aspirin was associated with small increases in systolic blood pressure (BP) (average 1.5 to 2.1 mm) and diastolic BP (0.5 to 0.6 mm), depending upon whether maximal or last available readings were used. Blood urea nitrogen and uric acid levels were also increased, but by less than 1.0 mg%. Subjects with marked hypertension or renal insufficiency had been excluded from the trial so that the clinical importance of these observations for such subjects or for any subjects treated over more prolonged periods is not known. It is recommended that patients placed on long-term aspirin treatment, even at doses of 300 mg per day, be seen at regular intervals to assess changes in these measurements.

Sodium in Buffered Aspirin for Solution Formulations:
One tablet daily of buffered aspirin in solution adds 553 mg of sodium to that in the diet and may not be tolerated by patients with active sodium-retaining states such as congestive heart or renal failure. This amount of sodium adds about 30 percent to the 70 to 90 mEq intake suggested as appropriate for dietary treatment of essential hypertension in the 1984 Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure.[8]

Dosage and Administration:
Although most of the studies used dosages exceeding 300 mg daily, two trials used only 300 mg and pharmacologic data indicate that this dose inhibits platelet function fully. Therefore, 300 mg or a conventional 325 mg aspirin dose daily is a reasonable, routine dose that would minimize gastrointestinal adverse reactions. This use of aspirin applies to both solid, oral dosage forms (buffered and plain aspirin) and buffered aspirin in solution.

Systemic Hypertension After Cardiac Transplantation: Effect of Cyclosporine on the Renin-Angiotensin-Aldosterone System

MARC BELLET, MD, CHRISTIAN CABROL, MD, PAOLO SASSANO, MD, PHILIPPE LÉGER, MD, PIERRE CORVOL, MD, and JOËL MÉNARD, MD

Fifteen patients who had undergone cardiac transplantation and who had hypertension (164 ± 14/112 ± 13 mm Hg), aged 16 to 57 years (mean 39), were treated with cyclosporine, 8 ± 3 mg/kg/day, and prednisolone, 0.27 ± 0.1 mg/kg/day, for 63 to 788 days (mean 288) after transplantation. They were not given antihypertensive drugs. Before treatment, the mean urinary sodium level was 104 ± 48 mEq/day. Two discrete abnormalities accompanied their high blood pressure (BP): an increase in serum creatinine levels ($p < 0.05$) to values exceeding those measured just before transplantation (2.1 ± 1.0 vs 1.35 ± 0.54 mg/dl) with low creatinine clearance (61 ± 28 ml/min · 1.73 m^2), and a 15% increase in plasma volume (+445 ± 686 ml, $p < 0.02$). Urinary excretion of vanilmandelic acid and total metanephrines was normal. Supine plasma renin activity was also normal (0.78 ± 0.32 nmol/ml/hour). The stimulation of renin release after acute inhibition of converting enzyme by captopril was less marked than is usual in hypertensive subjects (0.86 ± 0.54 nmol/liter/hour). Captopril induced a smaller drop in BP than nifedipine (−8 ± 13/−6 ± 10 mm Hg vs −14 ± 11/−15 ± 10 mm Hg). Levels of plasma aldosterone, angiotensinogen and converting enzyme activity were all normal, 308 ± 147 pmol/liter, 712 ± 164 nmol/ml and 30 ± 6 mU/ml, respectively. It is concluded that hypertension is common in cardiac transplantation patients treated with cyclosporine, since 13 of our 15 subjects were normotensive before transplant. Further, such hypertension is characterized by an expansion of plasma volume and the absence of major abnormalities of the renin-angiotensin-aldosterone system, despite the potential nephrotoxicity of cyclosporine.

(Am J Cardiol 1985;56:927–931)

Cyclosporine is a potent orally active immunosuppressant drug used in human organ transplantation.[1] One of the most notable adverse effects of cyclosporine therapy is nephrotoxicity. Thus, after several months of therapy with high doses, focal glomerular sclerosis was observed with a low glomerular filtration rate and reduced plasma flow.[2]

Although 2 years after cardiac allografting the survival rate with cyclosporine treatment increased from 58% to 75% compared with conventional immunosuppressive therapy, most of the long-term survivors treated with cyclosporine after cardiac transplantation became hypertensive; this contrasts with the incidence of less than 20% among patients given conventional immunosuppressive therapy.[3] Systemic arterial hypertension has also been reported in patients treated with cyclosporine after bone marrow[4,5] or kidney transplantation.[6] The pathogenesis of this complication is not clear. Animal experiments and in vitro studies suggest that cyclosporine stimulates the renin-angiotensin-aldosterone system.[7,8]

After cardiac transplantation, allograft rejection does not interfere with renal damage caused by this drug, unlike what is observed after kidney transplantation.[9] We therefore investigated the renin-angiotensin-aldosterone system in a group of heart transplant recipients who were hypertensive and were being treated with cyclosporine.

Methods

The study included 15 patients (14 men, 1 woman), aged 16 to 57 years (mean 39). This group of long-term survivors of cardiac transplantation (63 to 788 days) was gleaned from a total of 40 adults who had undergone transplantation at the cardiovascular surgery center of the Pitié Hospital in Paris from October 1981 through January 1984, and were treated with cyclosporine combined with prednisolone.

In 20 of these 40 patients, mild or moderate hypertension developed; 15 of these 20 are the subject of this report. Permanent hypertension was diagnosed in all 15 on the basis of 3 ambulatory blood pressure readings above 140/90 mm Hg. Only 2 patients were known to have mild, intermittent hypertension before cyclosporine treatment. All patients were kept under observation in hospital for 3 days. The nature of the study was explained to them, and each patient gave informed consent. All patients had normal cardiac function

From the Service d'Hypertension Artérielle, Hôpital Broussais, and the Service de Chirurgie Cardio-Vasculaire, Hôpital de La Pitié-Salpétrière, Paris, France. Manuscript received February 27, 1985; revised manuscript received May 23, 1985, accepted May 28, 1985.

Address for reprints: Marc Bellet, MD, Hôpital Broussais, 96 rue Didot, 75674 Paris Cédex 14, France.

(New York Heart Association functional class I). Routine tests confirmed that no patient had any of the usual forms of secondary hypertension. Subjects were allowed water ad libidum and free sodium and potassium intake. Patients had either never been treated with antihypertensive drugs or had stopped treatment at least 2 weeks before admission to hospital. Cyclosporine had been administered at a daily dose of 8 ± 3 mg/kg body weight 1 month after surgery until the study and the levels of immunoassayable plasma cyclosporine during the study before the morning dose ranged from 62 to 280 ng/ml (mean 181.4 ± 67.6). Prednisolone was administered at a daily dose of 0.27 ± 0.1 mg/kg body weight.

The following protocol was used. On day 1, heart rates in the supine and upright positions were compared, plasma volume was determined and 24-hour urine samples were measured for volume and excretion of sodium, potassium, creatinine, vanilmandelic acid and total metanephrine (i.e., normetanephrine and metanephrine); standard blood measurements were assessed in samples from fasting patients. On day 2, an automatic Sentron monitor was set at 8 AM on the right arm of recumbent, fasting patients and programmed to record heart rate and blood pressure every 3 minutes until 12 PM. At 8 AM, after 1 hour of standing, venous blood samples were collected for measurement of plasma renin activity and plasma aldosterone. At 9 AM, after 1 hour of recumbency, other blood samples were drawn for estimation of plasma renin activity, plasma aldosterone, angiotensinogen and plasma converting enzyme activity. Finally, captopril was given orally (1 mg/kg body weight) and 3 hours later, plasma renin activity and plasma aldosterone were again measured with the patient still supine. On day 3, the blood pressure and heart rate monitor was again set in recumbent patients from 8 AM to 11 AM. At 9 AM, 1 capsule containing 10 mg of nifedipine was orally ingested by 14 patients. The period of blood pressure recording was shorter after nifedipine than after captopril, as the nadir of blood pressure reduction occurs faster with nifedipine than captopril.[10–12]

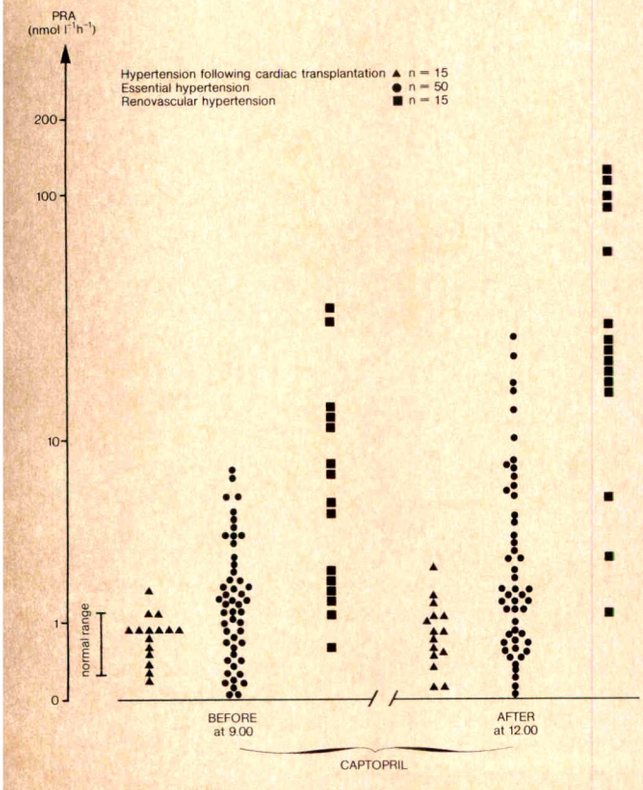

FIGURE 1. Variations in plasma renin activity (PRA) after a single dose of captopril (1 mg/kg body weight) in hypertensive cardiac transplantation patients treated with cyclosporine (**triangles**). Values were compared with those reported for patients with renovascular (**squares**) and essential hypertension (**circles**).[12]

Plasma renin activity and angiotensinogen were measured by angiotensin I radioimmunoassay,[13] plasma-converting enzyme activity was measured by the method of Cusmann modified by Lieberman[14] and plasma aldosterone, by direct radioimmunoassay.[15] Supine plasma volume was measured in 15 patients by the radioiodine-labeled serum albumin method, as previously described[16]; normal values were those reported by Hurley et al.[17] Urinary vanilmandelic acid and total metanephrines were measured by colorimetric and fluorimetric methods respectively. Blood pressure was measured by estimating the area under blood pressure-time curves divided by the period of recording. The maximal variations in heart rate were calculated from the average of the 7 values successively observed during the steepest drop in blood pressure after each drug.

Statistical comparisons were made by the Wilcoxon test for paired data, as appropriate. Correlation coefficients were obtained by the least-squares method. A p value <0.05 was considered statistically significant. Results are expressed as means ± standard deviation.

Results

The characteristics of the patients are given in Table I. After cardiac transplantation, an abnormal increase in serum creatinine levels was noted in 13 patients (2.10 ± 1 mg/dl vs 1.35 ± 0.54 mg/dl before transplantation, $p < 0.05$) combined with low creatinine clearance (61 ± 28 ml/min·1.73 m^2). Plasma volume rose significantly above the normal values measured in healthy volunteers (3,416 ± 687 ml vs 2,971 ± 321 ml, $p < 0.02$).[17] No 24-hour proteinuria was noted. Urinary excretion of vanilmandelic acid and total metanephrines was in the range of our normal laboratory values (less than 40 and less than 37 μmol per 24 hours, respectively).

Renin-angiotensin-aldosterone system: No stimulation of plasma renin activity was observed during cyclosporine treatment, either in the supine or upright positions (0.78 ± 0.32 and 1.97 ± 1.01 nmol/ml/hour, respectively; normal 0.27 to 1.00 and 0.54 to 2.31). After inhibition of converting enzyme, plasma renin activity was 0.86 ± 0.54 nmol/ml/hour and did not increase significantly (Fig. 1). Plasma renin activity values before captopril and 3 hours afterwards were compared with the values previously reported[12] for patients with renovascular and essential hypertension (Fig. 1). Angiotensinogen and plasma-converting enzyme activity were normal, 712 ± 164 nmol/ml (normal 617 to 925) and 30 ± 6 mU/ml (normal 23 to 38) respectively. Plasma aldosterone in the supine position was 308 ± 147 pmol/liter (normal 140 to 336), and after orthostatic stimulation, 1,346 ± 61 pmol/liter (normal 420 to 840). After converting enzyme inhibition, it decreased to 137 ± 61 pmol/liter ($p < 0.01$).

Blood pressure: Nifedipine significantly reduced blood pressure, from 140 ± 13/91 ± 14 mm Hg to 126 ± 13/76 ± 14.5 mm Hg ($p < 0.005$/$p < 0.005$). Captopril reduced it, from 147 ± 19/94.5 ± 17 mm Hg to 139 ± 17/89 ± 15 mm Hg ($p < 0.05$/$p < 0.05$). Although the

decrease in systolic blood pressure after nifedipine was not different from the drop after captopril, diastolic blood pressure fell more steeply after nifedipine ($p < 0.01$) (Fig. 2).

Heart rate: Heart rates in the supine and upright positions were compared in 14 patients. A maximal increase from 85 ± 11 to 98 ± 11 beats/min ($p < 0.02$) was observed after 15 minutes in the upright position, for a drop in blood pressure of 10 ± 13/4 ± 6 mm Hg ($p < 0.02$/$p < 0.05$). The hypotensive action of nifedipine was accompanied by tachycardia; heart rate increased from 83 ± 10 beats/min to 93 ± 9 beats/min ($p < 0.02$), an acceleration not observed with captopril (80 ± 10 to 82 ± 11 beats/min) (Table II).

Correlations: Whatever the conditions attending measurement of plasma renin activity, the latter never correlated with plasma volume, the drop in blood pressure after nifedipine or captopril, or the plasma cyclosporine level, neither did blood pressure correlate with renal insufficiency.

Discussion

The present study of 15 hypertensive heart transplant recipients showed that cyclosporine did not stimulate their renin-angiotensin system. This contradicted the results of previous in vitro experiments showing that 8.10^{-6} *M* cyclosporine stimulated renin production by 43% in rat kidney cortex slices[8]; in vivo, 25 or 20 mg/kg of cyclosporine daily also raised plasma renin activity levels in dogs and rats after several days.[7] These results therefore suggested that cyclosporine affects the renin-angiotensin system, and consequently raises

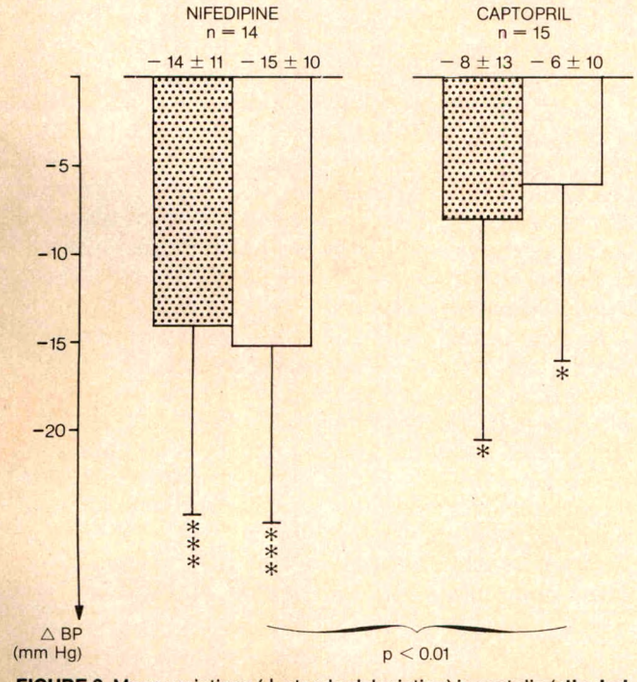

FIGURE 2. Mean variations (± standard deviation) in systolic (**stippled bars**) and diastolic (**clear bars**) blood pressure (BP) recorded 2 hours after 10 mg of nifedipine and 3 hours after 1 mg/kg of captopril, in long-term survivors of cardiac transplantation in whom hypertension subsequently developed. ***$p < 0.005$; *$p < 0.05$.

blood pressure. Here, plasma renin activity values in the recumbent position were within our normal range, and no abnormality was noted after orthostatism. After captopril, which abolished the negative feedback normally exerted by angiotensin II on renin release,[18] there was an increase in plasma renin activity that varied very slightly from patient to patient, and was confirmed by the finding that captopril caused a smaller drop in blood pressure than nifedipine. Our results agree with those of Myers et al,[2] who found no difference in the plasma renin activity levels of cyclosporine-treated patients compared with those of heart transplant recipients treated by conventional therapy. With regard to angiotensinogen, we found normal values, suggesting that prednisolone did not help to generate post-cyclosporine hypertension.[19] Plasma aldosterone values were within our normal range in the supine position, after stimulation by orthostatism and after inhibition by captopril, thus rendering the hypoaldosteronism described by Adu et al[20] unlikely under our conditions. Moreover, none of our patients had hyperkaliemia.

Thompson et al[21] suggested that an aberration in blood pressure control by the central nervous system intervenes in blood pressure regulation, because the heart remains denervated 1 and even 2 years after transplantation.[22] We did not confirm this in our experiments. Urinary excretion of vanilmandelic acid and total metanephrines were in the range of our normal values. The baroreflex regulation of heart rate persisted, since it was raised by both the orthostatic position and by the fall in blood pressure after nifedipine. As is usual in hypertensive patients,[11] the heart rate did not increase after captopril administration. Nifedipine treatment, however, did increase the heart rate in such patients.[10,11] The decrease in blood pressure observed in one of these last studies[10] was roughly similar to that induced by captopril in our patients. Some investigators[23] have attributed the absence of tachycardia after captopril to stimulation of the parasympathetic activity. However, as our patients had a denervated heart which did not respond to atropine,[22] the present results provide reason to believe that stimulation of parasympathetic activity by inhibition of the renin-angiotensin system is not responsible for the absence of tachycardia after captopril.

In conclusion, a state of stimulation of the renin-angiotensin system is improbable in heart transplant patients who become hypertensive. The abnormalities we observed in the laboratory tests of such patients were minor fluid retention (+15%) and renal impairment. Poor adaptation of the renin-angiotensin system to fluid retention may be partly responsible for the increase in the blood pressure in our patients[24]; further investigations are needed before any imbalance between sodium status and renin release can be demonstrated.

Acknowledgment: We are indebted to Dr. T.T. Guyenne and Prof. J.M. Alexandre for their invaluable assistance, and to C. Hallé, who typed the manuscript.

Ventricular Performance in Human Hearts Aged 61 to 73 Years

J.V. NIXON, MD, HUGH HALLMARK, MD, KIM PAGE, MS, PETER R. RAVEN, PhD, and JERE H. MITCHELL, MD

The effects of increasing and decreasing cardiac preload by 15% on the left ventricular (LV) performance of 11 carefully screened normal subjects aged 61 to 73 years were examined. Comparisons were made with 11 subjects aged 21 to 28 years. Two-dimensional echocardiograms were obtained before and at the termination of 5 degrees of head-down tilt for 90 minutes and at the termination of graded lower body negative pressure to −40 mm Hg. Heart rates and blood pressures were unchanged after physiologic interventions. Changes in LV end-diastolic and stroke volumes were similar but of a smaller magnitude in the older subjects compared with changes in younger subjects. When LV end-diastolic volumes obtained at each extreme of preload variation were compared, the range of mean change was less in the older (23 ml, 26%) than in the younger subjects (31 ml, 41%). Control LV end-diastolic and end-systolic volumes were greater in the older subjects. This study shows that despite larger control LV volumes, alterations in preload produce changes in the LV end-diastolic and stroke volumes of these older subjects that conform to the normal LV function curve, but that these responses are diminished compared with changes in younger subjects, suggesting an age-related change in diastolic stiffness.

(Am J Cardiol 1985;56:932–937)

Both experimental and human studies have shown that aging of the heart produces characteristic changes in different parts of the cardiac cycle.[1–8] Experimental studies of senescent myocardium have shown differing findings regarding both systolic and diastolic stiffness,[1–4] although prolonged contraction duration[3–6] and attenuated inotropic responses to catecholamines[6–8] are consistent findings. Human studies have also produced differing conclusions in older subjects both at rest and during dynamic exercise.[9–11] These differences may be partially attributed to the difficulty in identifying an elderly population that is free of significant intrinsic cardiac disease and, in particular, coronary artery disease.[11]

Recent noninvasive studies in our laboratory have defined the extreme ranges of the relation between left ventricular (LV) end-diastolic and stroke volumes (i.e., the Frank-Starling curve) in normal young subjects and in certain subsets of patients.[12,13] This study examines the effects of large variations in cardiac filling volume on the LV performance of a group of elderly subjects screened to exclude as comprehensively as possible the presence of intrinsic cardiac disease and, in particular, coronary artery disease. Comparisons were made with normal young subjects to define the differences, if any, in the response of the aging left ventricle to large variations in preload.

Methods

Subjects: Studies were carried out in 11 volunteer subjects, aged 61 to 73 years, who were screened to exclude as comprehensively as possible intrinsic cardiac disease. The screening procedure was as follows: Asymptomatic persons from area-aged programs were recruited. Those with a negative history, normal results on physical examination, and normal electrocardiographic findings at rest underwent serial test evaluations to exclude the existence of coronary artery disease by Bayesian analysis.[14] The reported prevalence of coronary artery disease in this asymptomatic age group ranges from 11 to 81%.[15] Data from our laboratory and other laboratories show maximal stress testing to have a sensitivity of 71% and a specificity of 92% for the diagnosis of coronary ar-

TABLE I Rest Heart Rates, Arterial Pressures, End-Systolic Wall Stress and End-Systolic Stress/Length Ratios in Young and Old Subjects

	Subjects		
	Young	Old	p
Heart rate (beats/min)	56 ± 3	59 ± 1	NS
Blood pressure (mm Hg)			
Systolic	108 ± 3	126 ± 4	<0.005
Mean	79 ± 2	94 ± 3	<0.005
Diastolic	65 ± 2	75 ± 3	<0.02
Wall stress (dynes/cm^2)	68 ± 5	78 ± 6	NS
Stress/length ratio	22 ± 1	24 ± 2	NS

All values are expressed as mean ± standard error of the mean.
NS = not significant.

tery disease.[16,17] After a stress test showing negative results in these subjects, the probability of the existence of coronary disease decreases to 4 to 57%. Bartel et al[18] reported that fluoroscopically detected coronary artery calcification has a sensitivity of 56% and a specificity of 97% for the diagnosis of coronary artery disease. In subjects with a negative result on fluoroscopy after a negative stress test result, the likelihood of the existence of coronary artery disease decreases again to 2 to 37%. While not eliminating the likelihood of the existence of coronary disease, this is an acceptable minimal range of prevalence for the disease. Furthermore, evaluation by 2-dimensional echocardiography of LV segmental wall motion as reported by our laboratory was also carried out.[19] The 11 subjects had no echocardiographic evidence of segmental wall motion abnormalities at rest or during the interventions of head-down tilt and lower body negative pressure.

Eleven subjects, aged 21 to 28 years, were studied for comparison. Details of the study were explained to each of the elderly and young subjects and they gave informed written consent.

Echocardiograms: The echocardiographic techniques and the methods and accuracy of measurements used in our laboratory have been described in detail.[13] Other echocardiographic measurements used in this study were meridional LV wall stress, where wall stress = systolic pressure × end-systolic diameter (ESD)/4 × wall thickness (1 + wall thickness/ESD) dynes/cm^2,[20] and systolic stress-dimension ratio, expressed as meridional wall stress/ESD ratio.[21]

The heart rate was determined from simultaneous electrocardiographic recordings. Blood pressure was recorded at 1-minute intervals throughout each intervention by Narco Bio-Systems programmed electrosphygmomanometer and recorded on a strip-chart recorder. Previous studies have demonstrated good agreement between these studies and auscultatory readings.[12,22] Mean arterial pressure was calculated as diastolic pressure + one-third of the pulse pressure.

Experimental protocol: The protocol of head-down tilt and graded lower body negative pressure used to increase and decrease LV preload has been described in detail.[13] Measurements from echocardiograms obtained before and at the termination of each preload variation were compared. Five degrees head-down tilt for 90 minutes produces a transient increase in central venous pressure of 2.5 cm H_2O, with a return to baseline when the left ventricle reaches its maximal size.[22] Graded lower body negative pressure to −40 mm Hg produces venous pooling with a progressive increase in leg volume of 500 to 700 ml and a transient decrease in central venous pressure of 5 cm H_2O.[22]

On a separate occasion, 6 of the older subjects underwent 5 degrees of head-down tilt for 6 hours to determine whether the time sequence of the response of the older left ventricle to prolonged head-down tilt was different in younger subjects. Leg volumes were estimated before and after 6 hours of tilt and calculated by Simpson's rule from measurements of leg circumferences at 12 well-defined points.[22]

Values determined before and at the termination of each intervention were compared and significant differences were determined by analysis of variance for single factor experiments having repeated measures.[23] When significant differences ($p < 0.05$) between groups were found, within-group differences were determined by the Student-Newman-Keuls multiple range test and values <0.05 were considered significant. Power curves and linear regression equations were determined from individual values of stroke volumes and end-diastolic volumes to obtain LV function curves.

Results

Rest heart rates, systemic arterial pressures, end-systolic wall stress and end-systolic stress/length ratios are listed in Table I. The anticipated differences in arterial pressures associated with age were found. No significant differences were found between the young and the older subjects in rest heart rate, end-systolic wall stress and end-systolic stress/length ratio. Changes in LV dimensions, shortening fraction, mean velocity of circumferential fiber shortening, heart rate and blood pressure are summarized in Table II. There were no significant differences between control data in either subject group before head-down tilt and before lower body negative pressure.

In the young subjects, the changes after both head-down tilt and lower body negative pressure were identical to those found previously in our laboratory (Table II, Fig. 1). Significant changes included an 18% increase in end-diastolic volume and a 31% increase in stroke volume during head-down tilt, and a 16% decrease in end-diastolic volume and 22% decrease in stroke volume during lower body negative pressure (Fig. 2).

In the older subjects during head-down tilt, mean end-diastolic volume increased 8%, from 104 ± 9 to 112 ± 9 ml ($p < 0.001$) and mean stroke volume increased 13%, from 58 ± 6 to 65 ± 7 ml ($p < 0.01$) (Fig. 1 and 2). Mean end-diastolic diameter increased from 4.7 ± 0.2 to 4.8 ± 0.2 cm and mean ESD decreased from 3.3 ± 0.2 to 3.1 ± 0.3 cm. End-systolic volume, ejection fraction, mean velocity of circumferential fiber shortening, heart rate and blood pressure did not change significantly during head-down tilt (Table I, Fig. 1).

TABLE II Effects of Head-Down Tilt and Lower Body Negative Pressure on Young and Old Subjects

	Young Subjects				Old Subjects			
	Head-Down Tilt		LBNP		Head-Down Tilt		LBNP	
	Control	Intervention	Control	Intervention	Control	Intervention	Control	Intervention

ESD (cm)	3.2 ± 0.1	3.3 ± 0.1	3.2 ± 0.1	3.1 ± 0.1	3.3 ± 0.2	3.1 ± 0.3	3.3 ± 0.1	3.2 ± 0.1
SF (%)	0.30 ± 0.02	0.33 ± 0.01	0.30 ± 0.02	0.27 ± 0.01	0.30 ± 02	0.31 ± 0.02	0.30 ± 0.02	0.27 ± 0.01
Mean Vcf (circ/sec)	0.86 ± 0.05	0.91 ± 0.04	0.83 ± 0.05	0.82 ± 0.04	0.83 ± 0.06	0.84 ± 0.05	0.81 ± 0.06	0.78 ± 0.06
HR (beats/min)	56 ± 3	52 ± 3	53 ± 3	60 ± 4	63 ± 2	61 ± 1	59 ± 1	58 ± 4
Systolic BP (mm Hg)	107 ± 3	108 ± 3	107 ± 3	109 ± 4	126 ± 4	130 ± 5	131 ± 4	126 ± 4
Mean BP (mm Hg)	79 ± 2	80 ± 3	79 ± 2	83 ± 3	92 ± 3	94 ± 3	95 ± 3	90 ± 5
Diastolic BP (mm Hg)	65 ± 2	66 ± 3	65 ± 3	69 ± 3	75 ± 2	76 ± 2	77 ± 2	77 ± 2

All values are expressed as mean ± standard error of the mean.
BP = blood pressure; EDD = end-diastolic diameter; ESD = end-systolic diameter; HR = heart rate; LBNP = lower body negative pressure; SF = shortening fraction; Vcf = velocity of circumferential fiber shortening.

In the older subjects, during lower body negative pressure, mean end-diastolic volume decreased 15%, from 104 ± 9 to 89 ± 8 ml ($p < 0.001$) and mean stroke volume decreased 20%, from 59 ± 6 to 48 ± 5 ml ($p < 0.001$) (Fig. 1 and 2). Mean end-diastolic diameter decreased from 4.7 ± 0.2 to 4.4 ± 0.2 cm and mean end systolic diameter from 3.3 ± 0.1 to 3.2 ± 0.1 cm. End-systolic volume, ejection fraction, mean velocity of circumferential fiber shortening, heart rate and blood pressure did not change significantly during lower body negative pressure (Table I, Fig. 1).

When end-diastolic volumes obtained at each extreme of preload variation during head-down tilt and lower body negative pressure were compared, the range of mean change was less in the older than in the younger subjects. In the young subjects, the range in mean end-diastolic volume of 32 ml represented a range of change of 34% of the control end-diastolic volume at rest, and a 41% increase from the end-diastolic volume during lower body negative pressure. In the older subjects, the change in mean end-diastolic volume of 23 ml represented a range of change of 23% of the control end-diastolic volume at rest and a 26% increase from the end-diastolic volume during lower body negative pressure.

Individual data relating stroke volume to end-diastolic volume at rest and during both interventions in both subject groups are shown in Figure 3. In the young subjects, the data are consistent with previous reports from our laboratory, conforming to a normal LV function curve, best described by the power curve stroke volume equaling 0.83 end-diastolic volume$^{0.9}$ ($r = 0.87$, $p < 0.001$); this is not significantly different from the linear regression stroke volume equaling 0.6 end-diastolic volume + 0.9 ($r = 0.88$, $p < 0.001$). In the older subjects, the data conformed to a similar LV function curve best described by the power curve stroke volume equaling 0.58 end-diastolic volume$^{0.99}$ ($r = 0.88$, $p < 0.001$); this is not significantly different from the linear regression stroke volume equaling 0.6 end-diastolic volume + 3.9 ($p < 0.001$).

The changes in LV dimensions and leg volumes in the 6 older subjects who underwent head-down tilt for a prolonged period of 6 hours on a separate occasion are illustrated in Figure 4. The maximal increase in mean end-diastolic and stroke volumes were of the same magnitude as the previous study of 11 older subjects and occurred after 90 minutes, without further increase during the subsequent 4½ hours. Leg volume decreased from 7.4 ± 0.2 to 7.0 + 0.2 liters ($p < 0.05$), corresponding to a combined volume change (both legs) of 0.8 liter.

Discussion

This study shows that in normal older subjects, the response of the left ventricle to increases and decreases in preload of 15% produces changes that conform to a normal ascending LV function curve, but which are diminished when compared with changes in normal young subjects. When end-diastolic volumes obtained at each extreme of preload variation were compared, the elderly subjects had an increase of only 26% of their lowest end-diastolic volume during lower body negative pressure, whereas the young subjects had an increase

FIGURE 1. Circ = circumference.

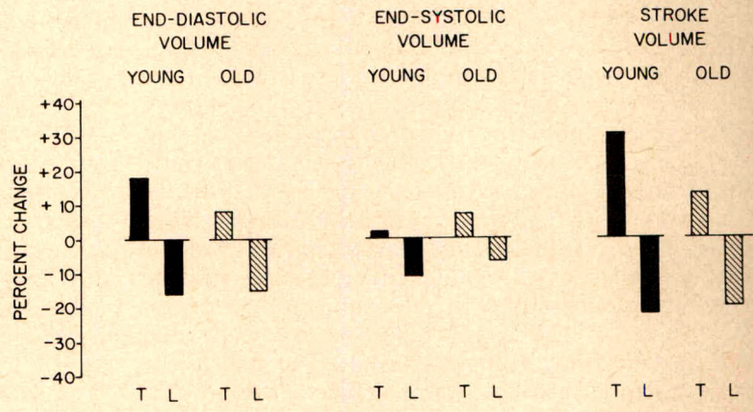

FIGURE 2. Percent changes in left ventricular end-diastolic, end-systolic and stroke volumes from control values during head-down tilt (T) and lower body negative pressure (L) in young and old subjects.

of 41%. Furthermore, the end-diastolic and stroke volumes of the older subjects ranged over a series of higher points on the normal Frank-Starling curve, despite body weights equivalent to those of the young subjects.

Previous studies carried out to determine the effect of age on the hemodynamic responses to various physiologic interventions have shown an attenuated heart rate and blood pressure response to head-up tilt, the Valsalva maneuver, the cold pressor test and static exercise.[24] A possible explanation for these altered responses was a reduction in baroreceptor activity with age as previously shown by Gribbin et al.[25] However, in our studies, no significant changes in heart rate or blood pressure occurred during either head-down tilt or lower body negative pressure.

These findings concur with those of Ebert et al,[26] who showed no changes in heart rate or blood pressure in subjects aged 50 to 59 years during graded lower body negative pressure to −40 mm Hg. Furthermore, they demonstrated a significant reduction in stroke volume during lower body negative pressure in their subjects compared with those of a young group of subjects. These

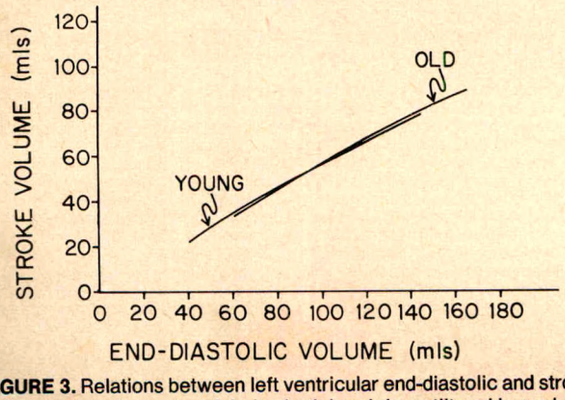

FIGURE 3. Relations between left ventricular end-diastolic and stroke volumes at supine rest and during both head-down tilt and lower body negative pressure in young and old subjects.

findings, obtained by impedance cardiography, concur with our echocardiographically estimated changes in stroke volume.

The findings in our study have several possible explanations, although some questions remain. Although it has been suggested that older subjects have less venous compliance changes during physiologic interventions,[24] the magnitude of central fluid shift demonstrated by a reduction in leg volume of a mean of 800 ml is identical to the magnitude found in younger subjects. This would appear to confirm that no comparative difference in magnitude of central fluid shift was a factor. It has been suggested that a greater central blood volume may exist in the older subjects.[27] Higher LV end-diastolic volumes at rest in our older subjects would comparative measurements of transthoracic impedance in young and older subjects by Ebert et al[26] showed no differences, suggesting that increased central blood volume is unlikely. The older human left ventricle may operate near its maximal volume, as suggested by Parker and Case.[28] They summarized several of their studies during various interventions with changes in blood volume and filling pressures and concluded that the human LV function curve reaches a plateau rapidly after relatively small increases in end-diastolic volume. Previous studies in normal young subjects in our laboratory do not support this concept having findings similar to those of the young subjects in this study.[12] Apparently, our findings in older subjects do not concur with this concept either. Figure 3 shows that while the range of changes in end-diastolic and stroke volumes is less than in the young subjects, the proportional changes in stroke volume with changes in end-diastolic volume are identical, without movement off the normal Frank-Starling curve. Furthermore, there is no evidence that the plateau phase of the curve has been reached in these older subjects.

The value of echocardiography in serially evaluating changes in LV performance during acute interventions is well accepted. The calculation of LV volumes is based on the assumption that the left ventricle is always ellipsoid in shape and the minor diameter is always half the major diameter.[12] At the extremes of ventricular volumes encountered in our subjects, the ventricle may have altered its shape, becoming more ellipsoid at small volumes and more spherical at higher volumes. The regression equation of Teichholz et al[29] was derived from a series of angiographically normal ventricles over a wide range of volumes than those encountered in our patients during the various interventions. Furthermore, estimations of ventricular volumes in all types of cardiac disease by 2-dimensional echocardiography have shown a better correlation with angiography.[30] However, the linear dimensional changes are identical to the volume changes, the regression equation used is valid over the ranges of ventricular volumes of our subjects, and evidence of the existence of coronary disease excluded subjects from the study. Thus, an intrinsic error in volume estimation would apply consistently to comparative values.

Considerable effort was made in this study to select older subjects for study who were free of significant intrinsic cardiac disease and, in particular, coronary artery disease. The use of serial test evaluations to determine prevalence of disease and, in particular, coronary artery disease, has been advocated as acceptable in a normal population, in which cardiac catheterization cannot be justified.[14] The screening procedure used for providing the subjects in our study was more thorough than some[10] and less thorough than others.[11] Without cardiac catheterization, however, the presence of coronary artery disease cannot be ruled out. Nevertheless, the selection of 11 subjects older than age 60 years, with a less than 2 to 37% likelihood of having coronary artery disease, and who had no echocardiographic evidence of segmental wall motion abnormalities at rest or during the interventions, appear to make up a suitable subset of subjects for study.

The differences in mean arterial pressures between the young and older subjects may serve to explain the differences in ventricular dimensions in the 2 groups. Should this be the case, one would expect significant differences in both end-systolic wall stress and the stress/length ratio between the 2 groups. Furthermore, there were no differences in mean heart rate between the 2 groups of subjects, either at rest or during the interventions of head-down tilt and lower body negative pressure.

Magnetic Resonance Imaging in Pulmonary Arterial Hypertension

ALAIN BOUCHARD, MD, CHARLES B. HIGGINS, MD, BENJAMIN F. BYRD III, MD, EUGENIO G. AMPARO, MD, LUCI OSAKI, RN, MS, and RICHARD AXELROD, MD

Magnetic resonance imaging (MRI) was used to examine the right ventricle and pulmonary arteries in 17 patients with pulmonary artery (PA) hypertension documented by cardiac catheterization. The study population consisted of 7 patients with primary pulmonary hypertension, 7 with Eisenmenger's syndrome and 3 with pulmonary hypertension secondary to lung disease. The MRI studies of patients were compared with those of 10 normal volunteers. Multislice gated transaxial images encompassed the right ventricle and central pulmonary arteries, showing the severity of right ventricular (RV) hypertrophy in proportion to the elevation of PA pressure and reversal of septal curvature when PA pressure approximated systemic pressure. End-diastolic RV wall thickness and mean pulmonary pressure correlated well (r = 0.79). MRI showed enlargement of PAs in all patients with PA hypertension. A magnetic resonance signal was present in the PAs throughout the cardiac cycle in patients with severe PA hypertension (more than 90 mm Hg) and was absent during systole in normal subjects. A signal within the PAs in systole is consistent with decreased flow velocity in patients with severe PA hypertension. MRI was useful in detecting each of the congenital anatomic defects in patients with Eisenmenger's syndrome.

This study indicates the potential of MRI for evaluating the severity of PA hypertension by providing direct measurements of RV wall thickness and PA diameter and by detecting abnormal intraluminal signal intensity during the cardiac cycle.

(Am J Cardiol 1985;56:938–942)

Magnetic resonance imaging (MRI) has emerged as a noninvasive method for visualization of cardiac structures.[1,2] Because MRI displays the blood pool as very low or no signal intensity with the spin echo technique, the walls of blood vessels and cardiac chambers are visualized without contrast medium.

This study was undertaken to evaluate the capability of MRI to define the anatomic features and origin of pulmonary artery (PA) hypertension and to assess the severity of PA hypertension.

Methods

Study population: The study population comprised 10 normal men, aged 28 to 44 years, and 17 patients with PA hypertension. The latter patients underwent cardiac catheterization before MRI study. Seven patients had primary PA hypertension. The 10 patients with secondary PA hypertension included 3 with a variety of parenchymal lung diseases (obstructive and interstitial) diagnosed on chest radiograph and pulmonary function tests and 7 with Eisenmenger's syndrome documented by the demonstration of congenital heart disease at angiography. The clinical and hemodynamic findings are given in Table I.

Magnetic resonance technique: The magnetic resonance imager for this study used a superconducting magnet operating at a field strength of 0.35 tesla and a resonance frequency for hydrogen of 15 MHz. This imager has been described in detail.[3] A multiplane selective irradiation technique was used for data acquisition and sectional (plane) images were reconstructed by the 2-dimensional Fourier transform technique. The slices were 7 mm thick. The reconstruction matrix was 256 horizontal and 128 vertical lines.

The imaging sequence was spin echo with echo delay times of 28 and 56 ms. First and second spin echo images were acquired at 5 adjacent anatomic levels during each acquisition. The repetition rate, or interval between sets of radiofrequency pulses, was determined by each subject's heart rate. In all subjects images gated to every heart beat were obtained. The gating system has been described.[4]

Data analysis: Ten to 15 adjacent transverse tomographic images were recorded in all subjects; these images extended through the level of the main PA and its bifurcation and through the heart (from the great vessels to the apex). Five adjacent sagittal images were obtained in 2 patients with Eisenmenger's disease. Images were analyzed to determine the presence and location of structural abnormalities (Table I). The septal curvature was described as convex, straight or concave toward the right ventricle.

The ventricular wall thicknesses were determined at end diastole (5 ms after the R wave of the electrocardiogram). A calibrated grid was available for superimposition on the images. The anterior wall of the right ventricle, septum and posterior wall of the left ventricle were measured along a line through the middle of each ventricle and perpendicular to the septum. A detailed description of the site and method for mensuration for MRI studies is available.[5] The septal thickness could not be determined in 2 patients with Eisenmenger's disease because of the presence of large ventricular septal defects. The main pulmonary trunk was measured in systole,

16	32M	TG,VSD	95 (95)	72 (72)	5	1.3
17	33F	DORV,VSD	96 (95)	72 (65)	3	1.0

Values in parentheses are systolic blood pressure values.
ASD = atrial septal defect; DORV = double outlet right ventricle; Dx = diagnosis; LD = lung disease; MPA = main pulmonary artery; MRI = magnetic resonance imaging; PDA = patent ductus arteriosus; PPH = primary pulmonary hypertension; RVWT = right ventricular wall thickness; TGV = transposition of the great vessels; VSD = ventricular septal defect.

on the transverse slice 1 cm caudal to the origin of the right PA. The ratio of the diameter of the PA to that of the aorta was determined at this same level. The ratio of the left descending PA to the descending aorta was taken at a more caudal level.

The magnetic resonance signal within the lumen of the PAs was determined on each of 5 images obtained during a single imaging period. These 5 multislice images corresponded to 5 phases of the cardiac cycle: end diastole; end diastole + 100 ms; end diastole + 200 ms; end diastole + 300 ms; and end diastole + 400 ms. Each of the images were examined for magnetic resonance signal within the lumen of the central PAs. The images extending up to 300 ms after end diastole occurred within the systolic phases of the cardiac cycle.

The presence of signal in the PAs was graded from 1 to 5 by the following criteria: 1/5 for PA signal present only on the image at end diastole and 2/5 for signal present on 2 images, and so forth, up to 5/5 for signal present on all 5 images. This determination was made on the second spin echo image (TE = 56 ms) because this image is more sensitive for intraluminal flow signal[1,2]; the assessment was made in the center of the PA lumen. All observations and measurements were made by 2 independent observers without knowledge of the results of the catheterization.

Statistical analysis was performed using standard linear regression and one way analysis of variance. Mean values and standard deviation are provided for all measurements.

Results

Normal findings: The transverse images at the level of the great vessels showed normal position and size of the ascending aorta and the main pulmonary trunk and its branches (Fig. 1). The diameters and the relation between these vessels are shown in Table II.

Transverse images taken from the same level but at different times during the cardiac cycle demonstrated a magnetic resonance signal in the PAs and aorta only on the end-diastolic image. During systole there was no signal within the lumens of the aorta or the PAs (Fig. 1).

In Figure 2 (left) normal cardiac chambers are shown. The septum has a crescent shape, with its convexity toward the right ventricle. Normal wall thickness measurements are listed in Table II.

Anatomic findings in patients with pulmonary hypertension: The main PA was enlarged in every patient with PA hypertension (Table I). The ratio of the diameter of the main pulmonary trunk to that of the ascending aorta and the ratio of the diameter of the left descending PA to that of the descending aorta were increased in all patients with elevated PA pressure (Table II). The magnetic resonance signal within the pulmonary artery (Fig. 3) was present in systole in all but 1 patient with primary PA hypertension and all but 1 patient with Eisenmenger's syndrome. This is in contradistinction to the absence of intraluminal signal in the ascending and descending aorta during systole.

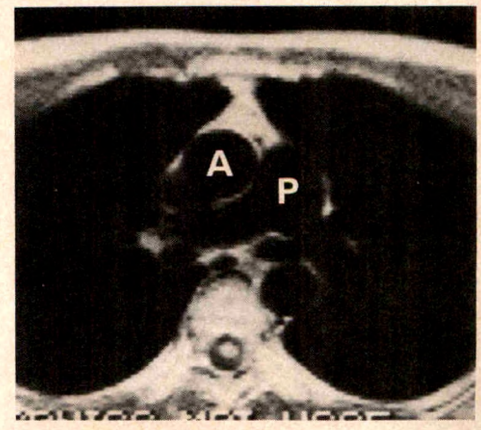

FIGURE 1. Transverse images at the level of great vessels in a normal patient. Image was acquired in systole. During systole there is absence of a magnetic resonance signal, indicating normal flow. A = ascending aorta; P = main pulmonary artery.

TABLE II Pulmonary Artery and Right Ventricular Dimensions as Measured by Magnetic Resonance Imaging

	Normals	1° PAH	2° PAH (LD)	2° PAH (Eisenmenger)	p Value
Main PAD (cm)	2.5 ± 0.4	3.9 ± 0.5*	3.6 ± 0.5*	3.7 ± 0.5*	0.05
Main PA/asc. aorta	0.9 ± 0.2	1.4 ± 0.2*	1.1 ± 0.1	1.4 ± 0.3*	0.05
Desc. LPA/desc. aorta	0.4 ± 0.1	1.1 ± 0.3*	0.8 ± 0.1*	1.0 ± 0.2*	0.01
RVWT (cm)	0.3 ± 0.1	1.2 ± 0.4*	0.6 ± 0.1	1.3 ± 0.3*	0.01
SWT (cm)	1.0 ± 0.1	1.2 ± 0.3*	1.2 ± 0.3	1.3 ± 0.5	0.05
PWT (cm)	1.0 ± 0.1	1.1 ± 0.2	0.9 ± 0.1	1.0 ± 0.3	NS

* Significant difference compared with values in normal subjects.
Values are mean ± standard deviation.
Asc. = ascending; Desc. = descending; Desc. LPA = descending left pulmonary artery; NS = not significant; PA = pulmonary artery; PAD = PA diameter; 1° and 2° PAH = primary and secondary pulmonary hypertension; PWT = posterior wall thickness of the left ventricle; RVWT = right ventricular wall thickness; SWT = septal wall thickness.

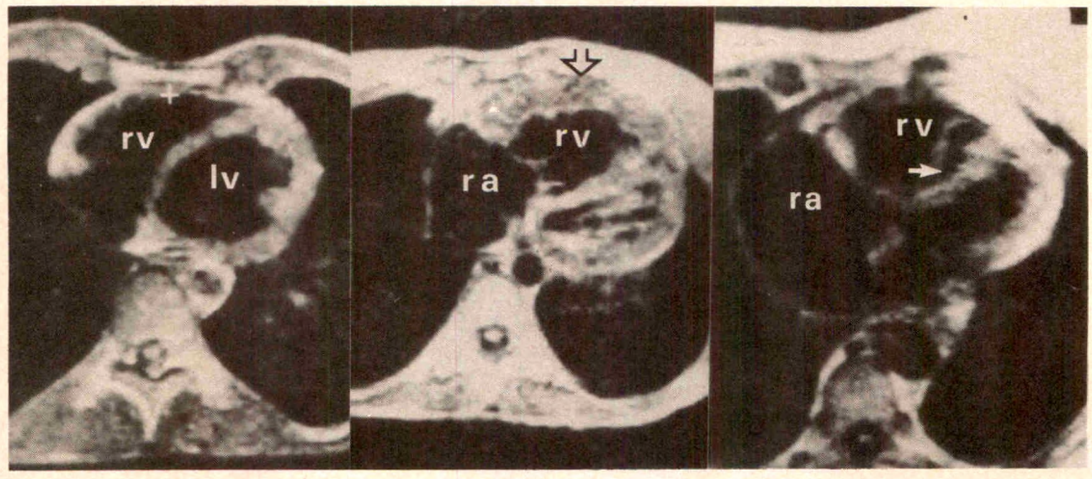

FIGURE 2. Transverse images at the level of the ventricle. **Left,** normal heart indicating where the anterior wall of the right ventricle (rv) was measured. **Middle,** gated image from a patient with primary pulmonary artery hypertension illustrating the severe hypertrophy of the right ventricular wall (**arrow**) and the straight septum. **Right,** concave septum (**arrow**) and enlarged right ventricle and right atrium (ra). LV = left ventricle.

The thickness of the anterior wall of the right ventricle was increased in direct relation to the severity of the PA systolic pressure (r = 0.76) (Table I, Fig. 2 [middle] and 4 [top]). The septal curvature was frequently altered in patients with PA hypertension; it was either straight or concave toward the right ventricle (Fig. 2). Septal curvature was abnormal in 6 patients with primary PA hypertension and 5 patients with Eisenmenger's syndrome. The right ventricle and right atrium were enlarged in all patients with PA hypertension.

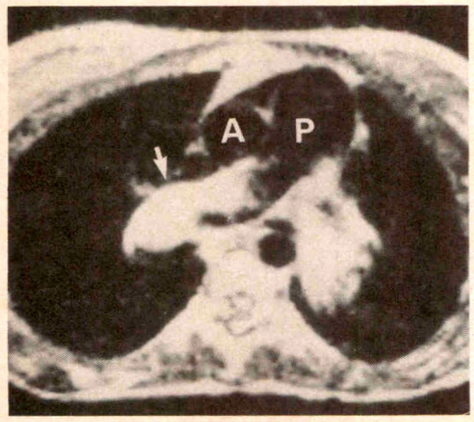

FIGURE 3. Transverse images at the level of great vessels in a patient with primary pulmonary artery hypertension. The main pulmonary artery (P) and its branches are enlarged and show intraluminal signal (**arrow**) during systole. Note the absence of signal in the aorta. A = ascending aorta.

Origin of pulmonary artery hypertension: In patients with Eisenmenger's syndrome, MRI was useful in determining the origin of PA hypertension. MRI detected the anatomic defects in all but 1 patient with Eisenmenger's syndrome. That patient had had a patent ductus arteriosus closed surgically 30 years before the study, and therefore had no anatomic defects other than sequelae of PA hypertension on the right ventricle.

Severity of pulmonary hypertension: As a measure of the severity of PA hypertension, the relation between right ventricular wall thickness and PA systolic pressure was defined (Fig. 4). The equation for the regression line of this relation is:

$$\text{PA systolic pressure (mm Hg)} = 59.2 \times \text{RV wall thickness} - 45.8 \quad (r = 0.76,\ \text{SEE} = 46 \text{ mm Hg},\ n = 17).$$

Figure 4 (bottom) shows the relation between RV wall thickness and mean PA pressure (r = 0.79, SEE = 16

mm Hg, n = 17). The regression equation was:

PA mean (mm Hg) = 10.1 × RV wall thickness + 30.

There was also a significant linear relation between the size of the main PA in systole and PA systolic pressure. The correlation coefficient and the standard error of estimate (SEE) for this relation were 0.76 and 21 mm Hg, respectively. The ratio of the diameter of the main pulmonary trunk to the ascending aorta showed a poorer correlation with systolic PA pressure (r = 0.59, SEE = 32 mm Hg). As another index of severity, we analyzed the septal curvature. When PA systolic pressure was plotted against septal curvature, every patient with pressure greater than 90 mm Hg had either a straight or concave septum (Fig. 5).

In most patients with PA hypertension a magnetic resonance signal was present in the PA throughout systole. When the frequency of intrapulmonary signal at the 5 phases of the cardiac cycle was compared with systolic PA pressure, only 1 patient with a pressure greater than 90 mm Hg showed the normal pattern consisting of intraluminal signal confined only to the end-diastolic image. Only 1 patient with pressure less than 90 mm Hg had pulmonary artery signal on the images obtained during systole (Fig. 6).

Discussion

MRI with electrocardiographic gating defined several characteristic anatomic features in patients with PA hypertension. The main PA was enlarged in all the patients with PA hypertension, including those with mild elevation of PA pressure. In our study population systolic PA pressure and diameter of the main PA correlated well (r = 0.76, SEE = 21 mm Hg, n = 13).

An interesting finding was the presence of PA signal during systole in patients with severe PA hypertension. Generally, blood flowing in a laminar fashion at normal velocity in large blood vessels causes no intraluminal magnetic resonance signal during systole. In this study, none of the normal subjects had magnetic resonance signals in the PAs during systole. In severe PA hypertension, it is expected that blood will be flowing at lower velocity and, consequently, cause intraluminal signal. In fact, 11 of the 12 patients with a systolic PA pressure greater than 90 mm Hg had magnetic resonance signal in their PAs during systole. This low flow situation may be the cause or the result of thrombosis within the PAs. In a recent study[6] lung tissue obtained at autopsy from 56 patients with primary PA hypertension revealed thrombotic material within the PAs in 57% of the

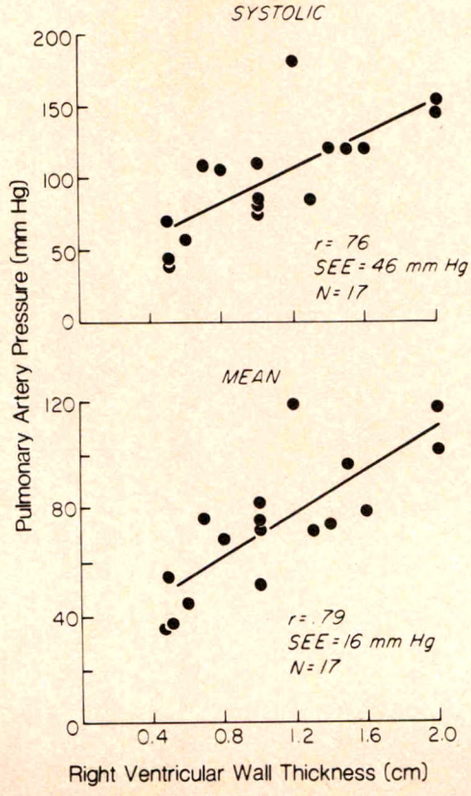

FIGURE 4. Top, relation between systolic pulmonary artery pressure and right ventricular wall thickness. **Bottom,** relation between mean pulmonary artery pressure and diastolic right ventricular wall thickness.

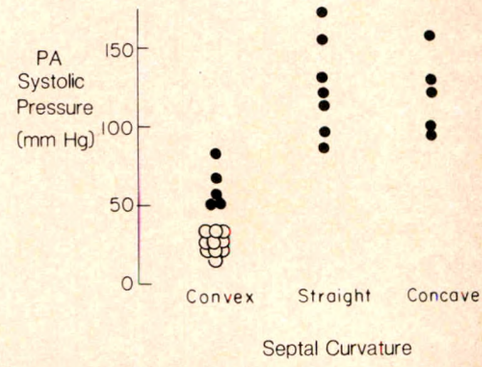

FIGURE 5. Relation between systolic pulmonary artery (PA) pressure and septal curvature. Patients with pressure greater than 90 mm Hg had either a straight or concave septum. **Open circles** represent values from normal volunteers, where pressures were not measured but assumed to be normal on the basis of physical examination.

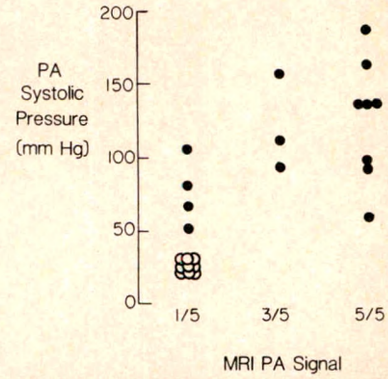

FIGURE 6. Relation between systolic pulmonary artery (PA) pressure and intraluminal signal on magnetic resonance images. 1/5 = signal only during diastole; 3/5 = signal present to midsystole; and 5/5 = signal present throughout systole. **Open circles** as per Figure 4. Only 1 patient with a pressure greater than 90 mm Hg did not have signal during systole and only 1 patient with pressure less than 90 mm Hg had a signal throughout systole. MRI = magnetic resonance imaging.

cases. Consequently, one must differentiate the signal from slow flow from that produced by intraluminal thrombosis. This is usually possible, because thrombus causes intraluminal signal on the first echo image but the signal decreases in intensity on the second echo image. In contrast, slow flow usually produces no signal in the first echo image but substantial signal on the second echo image.[7]

Several investigators[8–12] have used noninvasive methods to predict the PA pressure. Systolic time intervals and the pattern of pulmonic valve motion on M-mode echocardiography have been inconsistent in their accuracy for predicting PA pressure. However, high-quality echocardiographic tracings cannot be recorded in every adult patient, especially in patients with lung disease.[13]

MRI detected a secondary cause of PA hypertension—Eisenmenger's syndrome. Its capability to detect anatomic defects in patients with congenital heart disease was shown in a previous study.[14]

The results of this study suggest that MRI may be a useful noninvasive technique for diagnosing the presence of PA hypertension and assessing its severity. In cases of Eisenmenger's syndrome, MRI detected the anatomic defects in these patients. Consequently, MRI may serve as a noninvasive technique for the diagnostic assessment of patients with suspected PA hypertension and provide insight into the cause and the severity of PA hypertension.

Early Cardiac Changes Related to Radiation Therapy

MARKKU J. IKÄHEIMO, MD, KARI O. NIEMELÄ, MD, MARKKU M. LINNALUOTO, MSc, MATTI J.T. JAKOBSSON, MD, JUHA T. TAKKUNEN, MD, and PENTTI J. TASKINEN, MD

To investigate the incidence and severity of possible radiation-induced cardiac changes, 21 women without heart disease were investigated serially by echocardiography and by measuring systolic time intervals before and up to 6 months after postoperative radiation therapy because of breast cancer. Radiation was associated with a decrease in fractional systolic shortening of the left ventricular (LV) minor-axis diameter, from 0.35 ± 0.05 to 0.32 ± 0.06 ($p < 0.005$), and in the systolic blood pressure/end-systolic diameter ratio, from 4.4 ± 1.2 to 3.9 ± 0.9 mm Hg/mm ($p < 0.005$). The mitral E point-septal separation increased, from 2.8 ± 1.5 to 4.2 ± 2.5 mm ($p < 0.005$). The preejection period/LV ejection time ratio of systolic time intervals increased, but only the decrease within 6 months after therapy was significant ($p < 0.005$). All these changes reflect slight transient depression of LV function, which became normalized within 6 months after therapy. Up to 6 months after therapy, a slight pericardial effusion was found in 33% of the patients. Hence, conventional radiation therapy appeared to cause an acute transient and usually symptomless decrease in LV function, and later, slight pericardial effusion in one-third of the patients. (Am J Cardiol 1985;56:943–946)

Radiation to the mediastinum causes cardiac changes. In autopsies and in clinical studies, fibrosis and thickening of the pericardium has occasionally led to pericardial concretion and tamponade,[1–7] myocardial fibrosis,[1,2,7–10] endocardial fibrosis sometimes causing valve disease,[1–3,7–9] and coronary artery disease owing to coronary artery fibrosis or accelerated atherosclerosis, or both.[1,2,7,10,11] However, most of these studies were performed retrospectively, several years after radiation therapy and usually because of Hodgkin's disease; thus, less information is available concerning acute cardiac changes and their incidence after radiation in humans. The present study investigates noninvasively the possible acute cardiac changes and their incidence during and after postoperative radiation therapy because of breast cancer.

Methods

Patients: Twenty-four consecutive women with breast cancer, treated with radical mastectomy but not with cytotoxic or other drugs, were investigated. Three patients were excluded from the study, 1 because of combined mitral valve disease and 2 because of difficulty in echocardiographic examination. In the remaining 21 women the ages ranged from 31 to 59 years (average 45). No patient had evidence of metastases at the time of the study. One patient had had chest pains 10 years previously when she used contraceptive pills, but no cardiac disease was found and she has since been symptomless. Another patient had occasional palpitations, but all other patients had no cardiac symptoms before radiation therapy. One patient was taking thyroxin substitution therapy because of previous thyroidectomy. Ten patients had undergone left-sided and 11 had undergone right-sided radical mastectomy before the study.

Four patients had slight mitral valve prolapse seen on echocardiography and at clinical investigation. Two patients had slight T inversions in chest leads V_1 and V_2 seen on electrocardiography before radiation. All other patients had normal cardiac status before radiation therapy.

All patients were treated with cobalt-60 gamma radiation from 2 frontal fields: 1 parasternal and 1 neck-axillary, with 10 × 400 rads every other day for 24 days. The operation field was radiated by 250-kV radiographs laterotangentially. The parasternal field was 8 × 16 cm from the upper margin of the sternum (Fig. 1). The radiation dose to the heart was estimated from the isodose curve superimposed on the transversal computerized tomographic picture of the heart (Fig. 2). The maximal dose to the base, right atrium and right ventricle of the heart was about 3,600 rads, and the corresponding cumulative radiation effect 1,467 rets or timedose-fractionation factor 79. The minimal dose to the heart in the radiation field was about 60% of the field dose.

The studies were done before and immediately after completion of the radiation therapy, and 3 and 6 months afterward. The investigation consisted of physical examination, a standard 12-lead electrocardiogram, chest x-ray,[12] measurement of systolic time intervals and echocardiography.

Systolic time intervals were measured with a Hewlett-Packard contact transducer 21050A and a multichannel ultraviolet recorder at a paper speed of 150 mm/s using a standard technique.[14] Measurements were averaged from 10 consecutive cardiac cycles.

Echocardiograms were recorded by the same echocardiographer using a standard echocardiographic technique and patient's position, with ATL Mark III 2-dimensional echocardiographic equipment at a paper speed of 50 mm/s. M-

mode measurements were made from 5 consecutive cardiac cycles according to the recommendations of the American Society of Echocardiography[13] without knowledge of the chronologic order of the recordings.

Statistical comparisons between different patient groups were made using a Student *t* test. Differences between serial measurements of variables were calculated using nonparametric statistical methods: Friedman's 2-way analysis of variance and Wilcoxon's test.

Results

Symptoms and physical examination: Two patients with pericardial effusion complained of slight exertional dyspnea. One patient had slight exertional dyspnea at 3 months after therapy, but there were no changes in the results of noninvasive study. One patient, in whom there was a slight depression in LV function, complained of dizziness and palpitation after therapy and another patient complained of fatigue 3 months after therapy. The other 16 patients (76%) were symptomless.

No friction rub was heard in patients with pericardial effusion. Diastolic blood pressures were higher in the patients with the right breast removed than in those with the left breast removed before radiation therapy (88 ± 14 vs 75 ± 7 mm Hg, $p < 0.05$) and 6 months after therapy (91 ± 15 vs 77 ± 7 mm Hg, $p < 0.05$). Systolic blood pressure decreased in patients with the right breast removed between the studies before and immediately after therapy, from 141 ± 25 to 127 ± 21 mm Hg ($p < 0.005$), and the difference was still significant between the studies before and 6 months after therapy (141 ± 25 vs 133 ± 26 mm Hg, $p < 0.05$). There were no differences or changes in heart rate except that 3 months after radiation the heart rate was faster in patients with than in those without pericardial effusion (83 ± 9 vs 72 ± 13 beats/min, $p < 0.05$). The blood hemoglobin, packed blood cell volume and serum calcium concentration did not change significantly between studies.

Electrocardiogram and chest x-ray: New electrocardiographic changes after therapy were seen in 4 patients (19%) (Fig. 3): T inversions in 3 and slight ST-segment elevation in 1. In the 3 patients with new electrocardiographic changes, fractional shortening and (in 1) preejection period/LV ejection time ratio (PEP/LVET) were abnormal immediately after radiation therapy and in 1 patient PEP/LVET also at 3 months. The only significant change noted in relative cardiac size measured from chest radiographs[12] was that it decreased in patients whose left breast was removed between the studies immediately after therapy and 3 months later, from 374 ± 55 to 347 ± 48 ml/m^2 ($p < 0.005$).

Echocardiography (Table I): No patients had regional LV wall motion abnormalities during 2 dimensional real-time study. Fractional shortening decreased between the studies before and immediately after radiation therapy (from 0.35 ± 0.05 to 0.32 ± 0.06 [$p < 0.005$]), and mitral valve E point-septal separation (EPSS) increased, respectively (from 2.8 ± 1.5 to 4.2 ± 2.4 mm [$p < 0.005$]) (Fig. 4). Fractional shortening increased again between the studies immediately after therapy and at 6 months, from 0.32 ± 0.06 to 0.35 ± 0.06 ($p < 0.005$). In our laboratory the intraobserver variation

TABLE I Changes in Echocardiographic Measurements and Systolic Time Intervals

	Left Atrial Diameter (mm)	LV EDD (mm)	LV ESD (mm)	SBP/ESD (mm Hg/mm)	FS	mVCF (circ/s)	EPSS (mm)	PEPI (ms)	LVETI (ms)	PEP/LVET Ratio
Before radiation	33 ± 6	48 ± 5	32 ± 4	4.4 ±1.2	0.35 ± 0.05	1.14 ± 0.22	2.8 ± 1.5	134 ± 13	417 ± 17	0.35 ± 0.05
After radiation	32 ± 5	48 ± 5	32 ± 4	3.9 ±0.9	0.32 ± 0.06	1.07 ± 0.17	4.2 ± 2.5	139 ± 12	412 ± 17	0.38 ± 0.05
3 months later	32 ± 5	47 ± 5	31 ± 4	4.2 ± 1.1	0.34 ± 0.04	1.13 ± 0.17	4.0 ± 1.7	136 ± 14	414 ± 13	0.36 ± 0.06
6 months later	33 ± 6	48 ± 4	31 ± 4	4.3 ± 1.3	0.35 ± 0.06	1.19 ± 0.28	3.9 ± 1.8	132 ± 9	418 ± 15	0.34 ± 0.04

* $p < 0.005$; † $p < 0.05$.
All values are expressed as mean ± standard deviation.
EDD = end-diastolic diameter; EPSS = mitral valve E point-septal separation; ESD = end-systolic diameter; FS = fractional shortening of left ventricular minor axis diameter; LV = left ventricular; LVETI = LV ejection time index; mVCF = mean velocity of LV circumferential fiber shortening; PEPI = preejection period index; PEP/LVET = preejection period/LV ejection time; SBP = systolic blood pressure.

for serial measurements of fractional shortening is 0.02 or less and of EPSS 2 mm or less in patients with normal cardiac size. In 16 patients the decrease of fractional shortening was 0.03 or more and in 8 patients the increase of EPSS was 3 mm or more. If 0.26 is taken as the lower limit of normal fractional shortening, it was found to be abnormal (0.25, 0.17 and 0.22) in 3 patients at the completion of therapy; in all other studies it was within normal limits. The systolic blood pressure/end-systolic diameter ratio decreased between the studies before and immediately after radiation therapy (from 4.4 ± 1.2 to 3.9 ± 0.9 mm Hg/mm [$p < 0.005$]), and increased again between the studies immediately after therapy and at 6 months (from 3.9 ± 0.9 to 4.3 ± 1.3 [$p < 0.005$]). There were no differences in echocardiographic results between patients with the right or left breast removed.

Seven patients (33%) had slight pericardial effusion: one immediately after radiation, one 3 months after and five 6 months after therapy (Fig. 3). There were no differences in results reflecting LV systolic performance between the patients with and those without pericardial effusion, except that changes in the systolic blood pressure/end-systolic diameter ratio were significant in those without than those with pericardial effusion.

Systolic time intervals (Table I): The PEP/LVET ratio increased insignificantly between the studies before and immediately after radiation, but decreased significantly between the studies immediately after radiation and 6 months after therapy, from 0.38 ± 0.05 to 0.34 ± 0.03 ($p < 0.005$) (Fig. 4). If 0.44 is taken as the upper limit of normal,[13] the PEP/LVET ratio was abnormal in 4 patients immediately after radiation and in 2 of these 4 patients 3 months after therapy (Fig. 3). There were no differences in systolic time intervals between patients with and without pericardial effusion, or between patients with the right and those with the left breast removed.

Discussion

Radiation may induce both acute and chronic cardiac changes. After accidental fatal radiation, acute changes include myocardial perivascular edema and hemorrhage, leukocytes scattered in the epicardium and pericardial effusion.[14–16] In therapy, radiation doses may still be enough to cause acute changes in ventricular function. Using echocardiography and measurements of systolic time intervals of the left ventricle, we discovered transient slight depression in LV function related to radiation therapy. Fractional shortening and EPSS[17] correlate fairly well with LV ejection fraction, the latter negatively, when the left ventricle is of normal size and contracts symmetrically, as in our patients. The systolic blood pressure/end-systolic diameter ratio may reflect LV myocardial contractility better than fractional shortening,[18] but because we did not manipulate the afterload, the message of this measurement is lim-

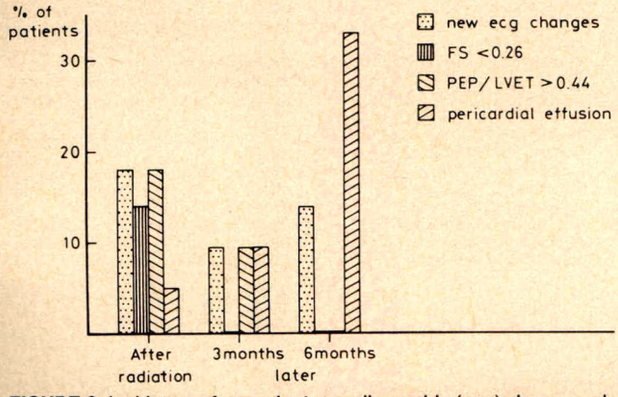

FIGURE 3. Incidence of new electrocardiographic (ecg) changes, abnormal fractional shortening (FS) and preejection period/left ventricular ejection time (PEP/LVET) ratio and pericardial effusion after radiation therapy, expressed as percentages of total number of the patients.

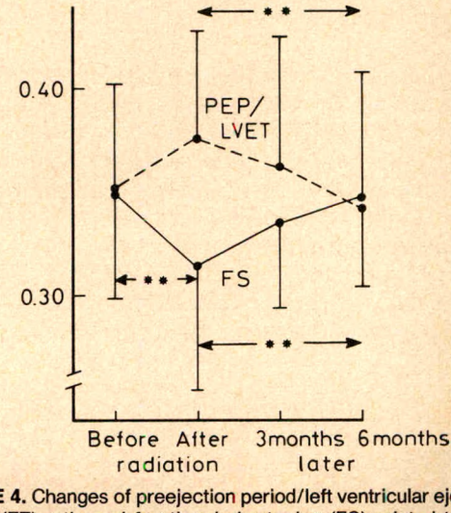

FIGURE 4. Changes of preejection period/left ventricular ejection time (PEP/LVET) ratio and fractional shortening (FS) related to radiation therapy, $p < 0.005$.

ited.[19] Blood pressures were measured from the right arm, so local changes may partially explain changes of blood pressure in patients with the right breast removed. However, the trend in changes of systolic blood pressure/end-systolic diameter ratio was equal in patients with the left breast removed as in the group as a whole.

Fractional shortening and systolic blood pressure/end-systolic diameter ratio decreased, and EPSS increased immediately after radiation therapy; they returned to normal levels within 6 months after radiation. The changes in the PEP/LVET ratio in our patients also reflect transient depression of LV function.[20] Although we did not have a control group who received radiation therapy elsewhere except in the heart, the changes in LV function were obviously caused by the direct effects of radiation in the heart. For instance, a possible peripheral vasodilation or increased sympathetic stimulation would increase and not decrease LV function. Our results are in agreement with those of Arom et al[21] in dogs. After a total dose of 5,000 rads, LV function decreased, expressed as cardiac output and stroke volume at rest and during volume overload. The measurements were lowest at 3 months after therapy and became normal within 7 months.

Only 3 patients had abnormal fractional shortening and 4 had abnormal PEP/LVET ratio after therapy. Although the acute cardiac effects of radiotherapy do not seem to cause clinical symptoms or problems in patients with normal cardiac function, the situation may be different in patients with cardiac failure. Only 1 patient had pericardial effusion immediately after radiation; thus, the acute cardiac effects of radiation appear to be more myocardial than pericardial.

Radiation may also lead to chronic cardiac changes months or usually years after exposure.[1,7,22] In the myocardium there may be fibrosis and in the pericardium thickening and effusion.[2,22–24] Myocardial changes may cause a decrease in LV size, suggesting restrictive cardiomyopathy and a decrease in systolic ventricular function, especially during exercise.[25] According to our results, acute changes in LV function disappear within 6 months after therapy and future control studies will show if LV size or function changes again.

Pericardial effusion was found in 33% of our patients, occurring mostly 6 months after therapy. In earlier studies its incidence has varied from 6 to 30%.[1,4,6,25] For instance, in the study of Applefeld et al[6] the incidence was 11%, but all the patients were symptomatic. Byhardt et al[4] found a 29% incidence of pericardial effusion using measurement of cardiac size from the chest radiographs, of which 86% had effusion within 1 year after therapy. Echocardiography is much more sensitive in detecting pericardial effusion than chest radiography, so the 33% incidence in our patients compares well with other reports. Of the patients with pericardial effusion, only 1 had depression of LV function after therapy (fractional shortening 0.22 and PEP/LVET 0.47), and the measurements reflecting LV function did not change significantly in those with pericardial effusion. Thus, the mechanism by which radiation causes a pericardial reaction may be different from that leading to a myocardial reaction.

Reproducibility of Left Ventricular Area and Volume Measurements Using a Computer Endocardial Edge-Detection Algorithm in Normal Subjects

DONALD A. CONETTA, MD, EDWARD A. GEISER, MD, LESLIE H. OLIVER, PhD, ALAN B. MILLER, MD, and C. RICHARD CONTI, MD

The variability of serially recorded 2-dimensional echocardiograms in normal subjects was determined. During a 2-week period, 10 normal subjects underwent echocardiography 5 times, in 2 laboratories, with use of different ultrasonographs. The video recordings were analyzed using a computer image analysis system (Quantic 1200) to provide standardized left ventricular short-axis areas and area ejection fraction (EF). Left ventricular volumes and volume EF were calculated. The 95% confidence limits of the percent difference for end-diastolic area and volume between 2 samples in a given subject were ±16.8 and ±16.7%, respectively. The limits for end-systolic area and volume were ±15.8 and ±17.0%, respectively. The 95% confidence limits for differences of area and volume EF between 2 recordings were ±12.8 and ±9.7%, respectively. No correlation was found between clinical grade (image quality) and the variability of area measurements. A good correlation (r = 0.98) was found between area and volume EF for any given subject over the 5 observations. These confidence limits are narrower than those previously recorded.

(Am J Cardiol 1985;56:947–952)

Two-dimensional (2-D) echocardiography is a noninvasive method for following changes of left ventricular (LV) function in patients with heart disease. Because no standard exists for accurately calculating LV volume in patients in vivo, definition of the day-to-day variability of 2-D echocardiographic measurements is important. A recent study[1] calculated the 95% confidence limits for percent change of end-diastolic and end-systolic volumes and change in ejection fraction (EF) on serial 2-D echocardiograms. The study group included 20 normal and 10 abnormal hearts. Measurement variability has been noted to be greater in normal than in abnormal hearts using several imaging techniques.[1–3] Thus, the confidence limits established from their mixed population may be narrower than those of a normal population. Also, the LV volumes in the previous study were calculated from manually defined endocardial areas that incorporated a potentially large component of variability related to observer bias and image quality. In the present study normal subjects underwent serial imaging to include the variability expected during routine clinical laboratory 2-D examinations. However, a computer image analysis system (Quantic 1200, Bruce Franklin Inc.) was used to provide LV area measurements. The objective of this study was to quantify the variability of serial measurements of 2-D LV cross-sectional areas and calculated volumes in a normal population using a computer image analysis.

From the University of Florida College of Medicine, Gainesville, Florida, Jacksonville Health Education Programs, Jacksonville, Florida. Manuscript received December 28, 1984; revised manuscript received May 17, 1985, accepted May 20, 1985.

Methods

Study design: The study group consisted of 10 adult volunteers, 5 men and 5 women, mean age 30 years (range 20 to 49). Entrance criteria were absence of clinical evidence for cardiovascular disease and a 2-D echocardiogram considered adequate for diagnostic purposes in our clinical laboratories. Five subjects underwent imaging with use of a Mark 500 ATL mechanical sector scanner at the Shands Teaching Hospital at the University of Florida, and 5 subjects underwent imaging with an Irex Systems IIIA phased-array scanner at the University Hospital of Jacksonville, Florida. Each subject underwent imaging at approximately the same time of day, in a semirecumbent, left lateral decubitis position, from the same intercostal space and by the same technician. While monitoring a lead II electrocardiogram, recordings were made of the LV midpapillary muscle, the short-axis image having the greatest short-axis diameter and the roundest endocardial

contour (papillary muscles excluded). An apical 4-chamber view was also obtained with the patient in the left lateral decubitus position. This view was recorded with good visualization of the lateral wall endocardium and vertical orientation of the ventricular septum in the field, and when maximal long-axis length and maximal minor-axis dimensions were considered present. Betamax and ½-inch VHS video tape recordings of 10 to 20 cycles were obtained over 9 days on a Monday, Wednesday, Friday, Monday, Wednesday schedule. The previously mentioned internal landmarks and review of previously recorded images of each subject were used by the technicians to match cross-sectional recordings from day to day. Instrument gain was adjusted to the lowest level that provided the most continuous endocardial border while avoiding bloom around endocardial targets and excessive echo dropout.

Image analysis: Images were considered adequate for analysis if approximately 60% or more of the endocardium could be visualized throughout the cardiac cycle. Each recording was graded by 1 observer on a 1+ to 4+ scale to provide an index of image quality. A grade of 1+ indicated that the endocardial borders could be discerned; however, as much as 40% of the endocardial border (not in adjacent quadrants) could be missing during several frames in the cardiac circle. A grade of 2+ indicated that 20 to 30% echo dropout occurred on several frames, and artifact or bloom around the endocardial border provided targets that were not true endocardium and potentially confusing to analysis. A grade of 3+ indicated a study in which the borders were nearly continuous throughout all frames of the cycle. Image dropout (10 to 20%) and artifact were minimal. A grade of 4+ indicated that the borders were continuous with no potentially confusing artifacts.

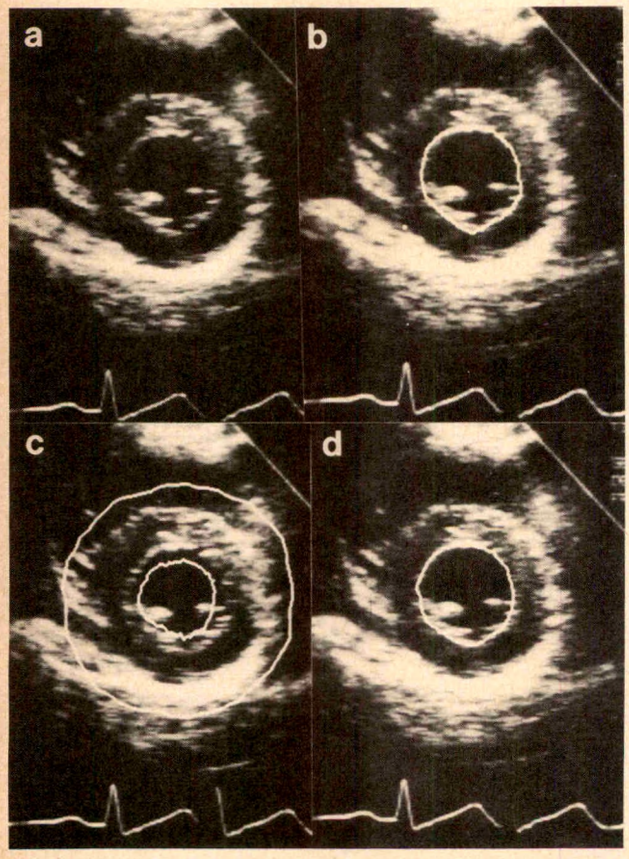

FIGURE 1. Subject 5. An end-systolic video frame showing: **a,** left ventricular short-axis image; **b,** manually traced endocardial border superimposed on the image in panel **a**; **c,** region of search superimposed on the image in panel **a**; **d,** computer-generated endocardial border superimposed on the image in panel **a.**

Cycles were selected randomly for analysis from daily recordings of each subject. The cycles were analyzed using a Quantic 1200 image analysis computer. The first step was the digitization of the selected video images and storage on digital disk. These stored cycles were then redisplayed, allowing the observer to select a single cardiac cycle for image analysis (Fig. 1a). The observer was asked to use a joystick-controlled cursor to calibrate the image using a centimeter scale from the video recording of the echo, and to designate an area of interest to direct the computer search for endocardial echoes. This latter step requires the observer to trace end-diastolic and end-systolic endocardial borders (Fig. 1b). Then, the manually traced end-diastolic border was expanded while the end-systolic border was contracted to provide the computer with a doughnut-shaped region of search (Fig. 1c). The manual tracings were not used in the remainder of the process. On each serial frame, the computer generated a set of borders using image-processing algorithms within the search region. The edge-detection algorithm first seeks endocardial echoes within the designated area by searching outward from the center of the left ventricle in a radial direction along 64 rays. As it searches, it uses an adaptive thresholding technique[4] to identify points where a shift in pixel gray level intensity occurs, consistent with a change in gray level that one would expect it to encounter when moving from LV cavity to myocardium. This set of radial points then provides a rough, static endocardial border. This rough border is modified by the computer using spatial and temporal smoothing algorithms (Fig. 1d). These procedures refine the rough borders by applying constraints to the sequential rough borders (frame to frame) that will conform to the physiologic, temporal and spatial properties of myocardial motion (i.e., the algorithm provides borders limited by the maximal expected distance a true endocardial point can move from frame to frame adjusted for heart rate [Fig. 2]).

The long-axis length was measured by digitizing a point in the center of the mitral valve plane and 1 at the midpoint of the cardiac apex and on end-diastolic and end-systolic frames from 3 consecutive cycles. Long-axis lengths were not available for 3 patients on 1 of the 5 observation days. The computer-generated borders, heart rate, computed end-diastolic and end-systolic areas and the long-axis lengths were stored on floppy disk for subsequent analysis.

Data reduction: The computed areas from 3 cycles recorded on the same day in the same subject were averaged to provide a single end-systolic and end-diastolic area, as well as an area EF observation. Area EF was computed as [(end-diastolic area − end-systolic area)/end-diastolic area] × 100. End-diastolic and end-systolic volumes were calculated as $V = \frac{5}{6}$ AL, where V = volume, A = short-axis area and L = long-axis length. Volume EF was computed as [(end-diastolic volume − end-systolic volume)/end-diastolic volume] × 100. The mean ± standard deviation of the areas, lengths, volumes, and area and volume EF observations for each subject and the group were calculated.

Differences, observed 95th percentile values and correlations: Absolute differences between any 2 end-systolic and end-diastolic areas, volumes, and area and volume EF observations for a subject were calculated. The mean differences were calculated and tabulated for each subject over the 5 observations in the study (Table I). Similarly, percent differences (disregarding sign) between any 2 end-systolic and end-diastolic area and volume measurements for a subject

were calculated. All within-subject area and volume percent differences and area and volume EF differences were sorted by computer and arranged in a percentile distribution to determine their observed 95th percentile values (Table II). The mean percent difference between area and volume determinations for each subject throughout the study was also computed (Table I). Each subject's mean percent area differences and mean area EF differences were regressed on the mean clinical grade of his 2-D images. Volume EF was regressed with the area EF from the same subject.

Ninety-five percent confidence limits for group data: The mean (± standard deviation) percent differences for end-diastolic area, end-systolic area, end-systolic volume, end-diastolic volume and mean differences for area and volume EF for the group were computed and tabulated (Table I). Ninety-five percent confidence limits for these group means were computed as: confidence limits = $t_{.05}$ (standard deviation)/$\sqrt{n}$, where t represents the t statistic for n-1 degrees of freedom at the 5% confidence level and n = the number of subjects.[1] (Table II).

Ninety-five percent confidence limits for individual subjects: The natural logarithms of end-diastolic and end-systolic area, end-diastolic and end-systolic volume, and area and volume EF values were entered into an analysis of variance to determine the within-subject's mean square differences (variance) over the 5 observations. This provided us with an estimate of the variability of serial recordings in a given subject. The 95% confidence limits for percent difference (variability) between observations of an echo measurement was calculated as $\log X_2 - \log X_1 = t_{(0.95,df)} \times \sqrt{2}$ (within-subject's variance), where X_1 and X_2 = 2 echo measurements in a given subject and df = degrees of freedom.[5,6] When the inverse log of both sides of the equation was taken, the computed 95% confidence limit equaled the ratio X_2/X_1, where X_2 is a measurement value that is greater than X_1. The $t_{(0.85,df)}$ = the 95th percentile value of the t statistic for the appropriate df. These data were converted to percent by taking the fractional portion of the X_2/X_1 ratio and multiplying by 100. Area and volume EF 95% confidence limits were converted from percent difference to difference by multiplying the confidence limit with the mean EF value computed by the analysis of variance (Table II).

Variability of repeated measurements of a cardiac cycle: One cycle from each subject was analyzed 3 times by the same observer using the Quantic 1200 to evaluate the variability (intraobserver) associated with the use of the computer image analysis system. The maximal percent differences noted between pairs of area and volume EF measurements were averaged. The 3 areas and area EF measurements for each subject were averaged and a coefficient of variation (standard deviation/mean) was calculated (expressed as percent). A mean coefficient of variation for the group was computed as the mean of all the subjects' individual coefficients of variation (Table III).

Results

The mean computer-generated midpapillary muscle short-axis end-diastolic area and end-systolic area were 16.39 ± 0.83 and 8.63 ± 0.47 cm^2, respectively. The mean area EF was 47.48 ± 5.13%. End-diastolic and end-systolic long-axis lengths were 8.4 ± 0.62 and 7.30 ± 0.61 mm, or a 14.04 ± 2.4% change during the cycle. The end-diastolic and end-systolic volumes calculated for these data were 116.93 ± 23.35 and 53.50 ± 12.11 ml, respectively. The volume EF was 54.50 ± 4.6%.

Regression of the area and volume EF revealed an excellent correlation (r = 0.98). However, regression of

mean clinical grade with end-diastolic area, end-systolic area and area EF revealed essentially no correlation, i.e., the r values were 0.14, 0.10 and 0.41, respectively.

Discussion

The variability of repeated measurements of LV volume and EF has been estimated using serial angiographic,[7,8] radionuclear ventriculographic and, more recently, echocardiographic[1–3,9,10] imaging in humans. Some studies[1–3] have shown greater variability of serial LV measurements in normal subjects than in patients with heart disease. Quantification of that variability in serial 2-D echocardiographic measurements not related to a disease process is necessary if 2-D echocardiography is to be used to follow changes in LV function. Serial LV volumes and EF were computed from an area-length equation using areas from manually traced endocardial borders of apical 4-chamber views on 2 days by Gordon et al[1] in 10 normal subjects and 20 patients with coronary artery disease. Their 95% confidence limits for percent change (computed as 2 times the standard deviation) were 15% between measurements of end-diastolic volume, 25% for end-systolic volume and 10% for EF to detect real changes, i.e., not owing to measurement error. However, confidence limits computed from their normal subject data was 16.3% for end-diastolic volume, 30% for end-systolic volume and 11.6% for EF. The present study was designed to simulate the variability one would expect from serial measurement of normal echocardiograms from different clinical laboratories. However, area measurements were made by a computer image analysis system to reduce variability due to observer bias in border identification.

Our study revealed that the predicted 95% confidence limits for percent differences encountered in the serial recording of echocardiograms for a given subject was 16.7% for end-diastolic volume, 17.0% for end-systolic volume and 9.70% for volume EF. While our individual and group 95% confidence limits for end-diastolic volume were similar to those found by Gordon et al,[1] those for end-systolic volume and volume EF were less than calculated for their normal subjects or their entire study group.

The differences between the confidence limits observed in both investigations may be related to a number of factors; the most significant is probably the method of border identification. The computer algorithm uses a thresholding technique to determine the peak gray levels indicating endocardial echocardiographic targets. On visual inspection, computer-generated borders appear to go through the midpoint of the leading edge of endocardial spots, a more important factor in end-systole when there is more coalescence and enlargement of the spots. Spot size or phosphor bloom around video images of echocardiographic targets have been related to gain amplification of the signal in the dynamic range of the echocardiograph.[11] Thus, this computerized method appears to choose consistent border points throughout the cycle that are relatively gain independent. In a previous study,[1] inner edge border points (the black-white endocardial interface) were used to reduce observer bias and increase consis-

tency of manually traced endocardial boundaries. This inner-edge technique has been noted to be gain-dependent in in vitro and in vivo studies.[12] Therefore, the larger variability of end-systolic volume noted by Gordon may be related to the gain dependence of their border identification method. However, the computer-generated areas are less open to subjective decisions made by the operator and therefore more consistent. This is shown in Table III, in which the maximal percent differences between values from repeated observation of the same cycle for the various area and area EF measurements ranged from 3.1 to 5.7%. The coefficients of variation for those repeated measurements ranged from 2.6 to 3.6%. The method for volume calculation in the prior study[1] required the imaging of an apical 4-chamber view. In this view the endocardial borders are less well seen in general (regardless of gain amplification) and this may have led to uncertainty of the location of the borders and contributed to the increased variability of volume calculations. Volume was calculated as $V = 8A(\frac{2}{3}\pi)L$, where A = long-axis area and L = long-axis length. In the present study, we used a short-axis view, which has more endocardial surface perpendicular to the interrogating echo beam and generally provides better definition of endocardial boundaries. Although 2 different area-length methods for determination of volume were used in each study, it is not clear that there is more variability associated with one or the other in terms of the volume calculations.

However, variability of area measurements will have a greater impact on volume and EF confidence limits, as area magnitudes (16.4 to 8.6 cm^2) and percent change (47.5%) during the cardiac cycle are greater than those for length (8.4 to 7.3 cm, 14%).

Our confidence limits of LV area and area EF are similar to those found for LV volumes and volume EF. The predicted 95% confidence of these measurements are very similar to the observed 95th percentile value measured from our study group. Also, there is an excellent correlation (r = 0.98) between area and volume EF. Similarly, the group area and volume-observed 95th percentile values and 95% confidence limits differed by 1% or less. In view of these findings, we propose that short-axis area and area EF could be used as indexes of LV function.

Our method has limitations: The use of LV short-axis cross sections, which may not be available in all patients, and the fact that our confidence limits were computed from an analysis of variance of measurements in a normal group. Although the limits are narrower than those previously observed,[1] other studies[1–3] have shown that the variability of serial measurements of LV volumes and EF can be greater in normal than in diseased hearts. Thus, the limits proposed by this study may not detect small differences between examinations because of disease in abnormal hearts. However, because of the significant variations in cardiac anatomy with different diseases that would affect area measurements differently and the different levels of ventricular dysfunction that can be found within a given category of cardiac disease, development of narrower confidence limits to detect smaller changes in abnormal hearts could be a complex and extremely difficult task. Therefore, the limits developed in this study may be the most clinically practical for computer-analyzed images.

Acknowledgment: We thank Duane Alsobrook, Nancy Raynard and Barbara Harrison for their technical help in obtaining the echocardiograms; Barbara Conetta, BS, and Linda Rolnitsky, MS, Statistician, Department of Medicine, Division of Cardiology, Columbia Presbyterian Medical Center, for statistical analysis; and Donna Singleton for manuscript preparation.

Schematic diagram of a Transdermal Therapeutic System placed in contact with the skin.

New **Catapres-TTS**®[1,2,3]

(clonidine) / Transdermal Therapeutic System

Hypertension

Actual size patches

THREE DOSAGE STRENGTHS...
Start with it in mild to moderate hypertension

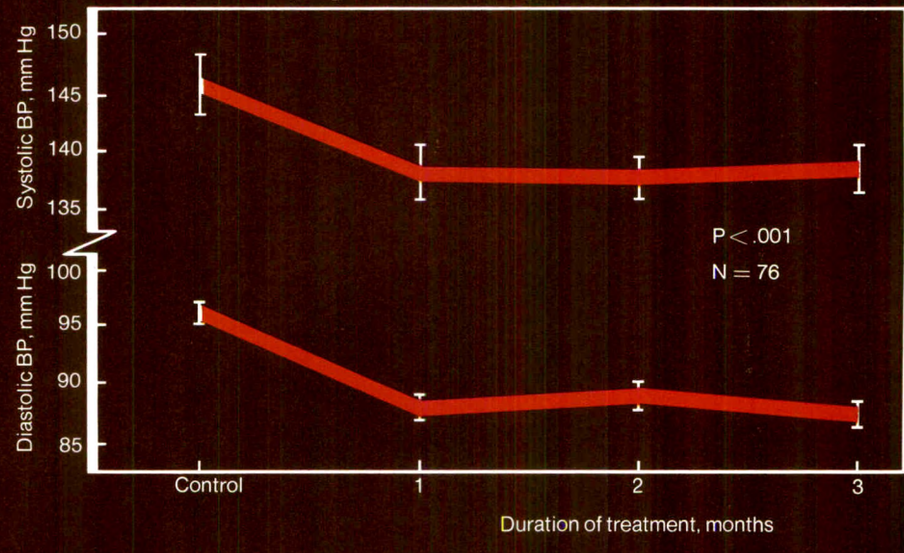
- Convenient once-a-week dosage to aid compliance.
- Effective blood pressure control with or without a diuretic.
- Steady-state blood levels — without the peaks and valleys of oral forms
- No diuretic-like biochemical effects.
- 24-hour blood pressure control 7 days a week.
- Central control of blood pressure.

Most common side effects are dry mouth and drowsiness, which tend to diminish with time, and mild erythema and pruritus associated with 7-day skin occlusion. After a mean duration of treatment of 24 weeks, contact dermatitis was observed in 16% of patients. This condition resolved upon discontinuation of therapy.

7 days of continuous therapy... a new age of compliance

Documented long-term efficacy

Systolic and diastolic BPs during control (placebo) and after 1, 2, and 3 months of treatment with clonidine administered transdermally. Values are means ± SEMs.[1]



Patch-to-patch applications

Steady-state blood levels— without the peaks and valleys of oral forms

Mean (n = 5) clonidine plasma concentration (ng/ml)—3.5 cm² Catapres-TTS patch.[2]

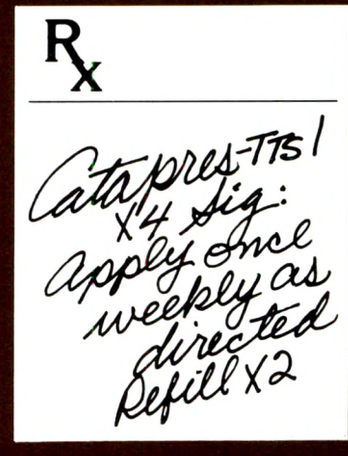
How to use Catapres-TTS®

Three Dosage Strengths for Individualized Therapy
Titrate to proper dosage with Catapres-TTS® alone

1. Start with #1. Replace with #2 and then #3 when necessary to achieve effective blood pressure control.
2. Catapres-TTS® is usually unaffected by showering or other routine daily activities. For some patients, use of an overlay is occasionally required to maintain adequate skin adherence.
3. Most common side effects are dry mouth and drowsiness, which tend to diminish with time, and mild erythema and pruritus associated with 7-day skin occlusion. Contact dermatitis was observed in 16% of patients (100 of 631) treated for a mean duration of 24 weeks. This condition resolved upon discontinuation of therapy.*



*Please refer to **Precautions** in prescribing information if considering substitution of oral clonidine hydrochloride in patients who develop skin reactions during Catapres-TTS® therapy.

Catapres-TTS®1,2,3

(clonidine) / Transdermal Therapeutic System

Hypertension

Actual size patches

THREE DOSAGE STRENGTHS...
Start with it in mild to moderate hypertension

The first once-a-week transdermal antihypertensive system

seven days of effective blood pressure control

Convenient once-a-week dosage to aid compliance.
Effective blood pressure control with or without a diuretic.
Steady-state blood levels—without the peaks and valleys of oral forms

Brief Summary of Prescribing Information

Contraindications: Catapres-TTS® (clonidine) should not be used in patients with known hypersensitivity to clonidine or to any other component of the adhesive layer of the therapeutic system.

Precautions: ***General:*** In patients who have developed localized contact sensitization to Catapres-TTS® (clonidine), substitution of oral clonidine hydrochloride therapy may be associated with development of a generalized skin rash.

Patients who develop an allergic reaction to Catapres-TTS® that extends beyond the local patch site (such as generalized skin rash, urticaria, or angioedema) oral clonidine hydrochloride substitution may elicit a similar reaction.

As with all antihypertensive therapy, Catapres-TTS® should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease, or chronic renal failure.

Withdrawal: Patients should be instructed not to discontinue therapy without consulting their physician. Sudden cessation of clonidine treatment has resulted in subjective symptoms such as nervousness, headache and sweating, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine concentrations in the plasma, but such occurrences have usually been associated with previous administration of high oral doses (exceeding 1.2 mg/day) and/or with continuation of concomitant beta-blocker therapy. Rare instances of hypertensive encephalopathy and death have been reported.

An excessive rise in blood pressure following Catapres-TTS® discontinuance can be reversed by administration of oral clonidine or by intravenous phentolamine. If therapy is to be discontinued in patients receiving beta-blockers and clonidine concurrently, beta-blockers should be discontinued several days before cessation of Catapres-TTS® administration.

Perioperative Use: As with oral clonidine therapy, Catapres-TTS® therapy should not be interrupted during the surgical period. Blood pressure should be carefully monitored during surgery and additional measures to control blood pressure should be available if required. Physicians considering starting Catapres-TTS® therapy during the perioperative period should be aware that therapeutic plasma clonidine levels are not achieved until 2 to 3 days after initial application of Catapres-TTS®.

Information for Patients: Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of a potential sedative effect of clonidine. Patients should be cautioned against interruption of Catapres-TTS® therapy without a physician's advice. Patients should be advised that if the system begins to loosen from the skin after application, the adhesive overlay should be applied directly over the system to assure good adhesion over its 7-day lifetime. Instructions for using the system are provided. Patients who develop moderate or severe erythema and/or localized vesicle formation at the site of application, or a generalized skin rash, should consult their physician promptly about the possible need to remove the patch.

Drug Interactions: If a patient receiving clonidine is also taking tricyclic antidepressants, the effect of clonidine may be reduced, thus necessitating an increase in dosage. Clonidine may enhance the CNS-depressive effects of alcohol, barbiturates or other sedatives. Amitriptyline in combination with clonidine enhances the manifestation of corneal lesions in rabbits.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a 132-week oral carcinogenicity study in rats, clonidine hydrochloride produced no carcinogenic effects at doses up to 300 times the maximum recommended human dose of Catapres-TTS® on a mg/kg weight basis.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Reproduction studies performed in rabbits at doses up to 3.1 times the maximum recommended daily human dose of Catapres-TTS® have revealed no evidence of impaired fertility or harm to the fetus due to clonidine hydrochloride. Studies in rats and mice revealed that doses of 500 mcg/kg/day and higher are embryotoxic. One rat study at doses of 15 mcg/kg/day (0.33 times the maximum recommended daily human dose) exhibited embryotoxicity. There are no adequate and well-controlled studies in pregnant women. Although animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: As clonidine is excreted in human milk, caution should be exercised when Catapres-TTS® (clonidine) is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children below the age of 12 have not been established.

Adverse Reactions: Most systemic adverse effects during therapy with Catapres-TTS® (clonidine) have been mild and have tended to diminish with continued therapy. In a 3-month, multiclinic trial of Catapres-TTS® in 101 hypertensive patients, the most frequent systemic reactions were dry mouth (25 patients) and drowsiness (12 patients).

Transient localized skin reactions, primarily localized pruritus, occurred in 51 patients. Twenty-six patients experienced localized erythema. This erythema and pruritus were more common in patients utilizing an adhesive overlay for the entire 7-day treatment period. Allergic contact sensitization to Catapres-TTS® was observed in 5 patients.

In additional clinical experience, contact dermatitis was observed in 100 of 631 patients (about 16 in 100) treated for a mean duration of 24 weeks.

The following less frequent adverse experiences were also reported in patients involved in the multiclinic trial with Catapres-TTS®:

Gastrointestinal: Constipation (1 patient); nausea (1); and change in taste (1).

Central Nervous System: Fatigue (6 patients); headache (5); lethargy (3); sedation (3); insomnia (2); dizziness (2); and nervousness (1).

Genitourinary: Impotence/sexual dysfunction (2 patients).

Dermatological: Localized vesiculation (7 patients); hyperpigmentation (5); edema (3); excoriation (3); burning (3); papules (1); throbbing (1); blanching (1); and generalized macular rash (1).

In additional clinical experience involving 3539 patients, less common dermatologic reactions have occurred, where a causal relationship to Catapres-TTS® was not established: maculopapular skin rash (10 cases); urticaria (2 cases); angioedema involving the face (2 cases), one of which also involved the tongue.

Oro-otolaryngeal: Dry throat (2 patients).
In long experience with oral clonidine hydrochloride, the most common adverse reactions have been dry mouth (about 40%), drowsiness (about 35%) and sedation (about 8%). In addition, the following adverse reactions have been reported less frequently:

Gastrointestinal: Nausea and vomiting, about 5 in 100 patients; anorexia and malaise, each about 1 in 100; mild transient abnormalities in liver function tests, about 1 in 100; parotitis, rarely.

Metabolic: Weight gain, about 1 in 100 patients; gynecomastia, about 1 in 1000; transient elevation of blood glucose or serum creatine phosphokinase, rarely.

Central Nervous System: Nervousness and agitation, about 3 in 100 patients; mental depression, about 1 in 100 and insomnia, about 5 in 1000. Vivid dreams or nightmares, other behavioral changes, restlessness, anxiety, visual and auditory hallucinations and delirium have been reported.

Cardiovascular: Orthostatic symptoms, about 3 in 100 patients; palpitations and tachycardia, and bradycardia, each about 5 in 1000. Raynaud's phenomenon, congestive heart failure, and electrocardiographic abnormalities (i.e. conduction disturbances and arrhythmias) have been reported rarely.

Dermatological: Rash, about 1 in 100 patients; pruritus, about 7 in 1000; hives, angioneurotic edema and urticaria, about 5 in 1000; alopecia, about 2 in 1000.

Genitourinary: Decreased sexual activity, impotence and loss of libido, about 3 in 100 patients; nocturia, about 1 in 100; difficulty in micturition, about 2 in 1000; urinary retention, about 1 in 1000.

Other: Weakness, about 10 in 100 patients; fatigue, about 4 in 100; headache, and discontinuation syndrome, each about 1 in 100; muscle or joint pain, about 6 in 1000 and cramps of the lower limbs, about 3 in 1000. Dryness, burning of the eyes, dryness of the nasal mucosa, pallor, weakly positive Coombs' test, increased sensitivity to alcohol and fever have been reported.

How Supplied: Catapres-TTS®-1 (clonidine), Catapres-TTS®-2 (clonidine) or Catapres-TTS®-3 (clonidine) is supplied as 4 pouched systems and 4 adhesive overlays per carton.

Catapres-TTS®-1 or Catapres-TTS®-2 is supplied in a shipper of 3 cartons.

Consult package insert before prescribing.

Nd-YAG Laser Fusion of Human Atheromatous Plaque–Arterial Wall Separations in Vitro

JOHN F. HIEHLE, Jr., BS, DONNA B.C. BOURGELAIS, BS, STANLEY SHAPSHAY, MD, FREDERICK J. SCHOEN, MD, PhD, DUCKSOO KIM, MD, and RICHARD SPEARS, MD

The hypothesis that thermal fusion of disrupted layers of atheromatous arterial wall can be achieved with a neodymium-yttrium aluminum garnet (Nd-YAG) laser was tested. Fresh postmortem human atheromatous plaque was separated from the underlying arterial wall to simulate a dissection in 1-cm^2 arterial wall sections. With the plaque and underlying arterial wall subsequently compressed between glass slides, 17 W of continuous-wave Nd-YAG laser radiation were delivered through an optical fiber to the luminal surface of the plaque over a 4-mm^2 area. Fusion of the plaque to the underlying arterial wall invariably occurred when tissue compression was applied during lasing and a thin blood film was present between the tissues. The load supported by tissue welds depended on plaque thickness, plaque composition, and exposure duration and was as great as 25 g. In postmortem, blood-filled, whole-artery segments, in which plaque had been completely separated from the media, this technique was applied intraluminally during angioplasty with a prototype balloon catheter. Lateral dispersion of Nd-YAG radiation from the termination of an optical fiber within the balloon allowed fusion of plaque to the underlying arterial wall during balloon inflation to 2 atm. Histologic examination of laser-treated tissues showed coagulation of tissues at the junction between the intimal plaque and media. It is concluded that thermal fusion of separated layers of atheromatous arterial wall can be achieved with Nd-YAG laser irradiation. This concept may be useful in the treatment of arterial dissections.

(Am J Cardiol 1985;56:953–957)

Percutaneous transluminal coronary angioplasty (PTCA) is an effective technique for the treatment of obstructive coronary atherosclerosis in many patients.[1–3] However, widespread application of PTCA is limited by the occasional complication of abrupt reclosure,[4] which necessitates operative standby during the procedure. Furthermore, the frequent occurrence of restenosis of the treated arterial segment[5] greatly limits the long-term clinical benefits to be expected from this procedure.

An important mechanism underlying successful PTCA dilatation of an atheromatous narrowing involves disruption of tissues within the arterial wall, including plaque fracture,[6–8] and angiography immediately after PTCA frequently reveals either a shaggy or hazy appearance or evidence of dissection.[9] Although arterial wall disruption from PTCA is usually well tolerated acutely, it is likely that abrupt reclosure occasionally results from an adverse extension of this mechanism, such as enlargement of a false channel and collapse of plaque tissue into the lumen. Furthermore, restenosis may be accelerated by a disrupted luminal architecture, which may provide a thrombogenic surface and a nidus for new plaque growth. Therefore, techniques that reduce disruption of the arterial wall and improve luminal geometry after PTCA may improve the safety and efficacy of the procedure. Recently, the use of laser irradiation to effect tissue-to-tissue adhesion experimentally in vessel repair and anastomosis has had considerable success.[10,11] We therefore tested the hypothesis that neodymium-yttrium aluminum garnet (Nd-YAG) laser irradiation could be used to produce adhesion between separated layers of human atheromatous plaque and underlying arterial wall.

Methods

Squares of arterial wall: An Nd-YAG laser (Advanced Biomedical Instruments), capable of 100 W of continuous-wave output at 1.06 μ was used for all studies. To evaluate the capability of Nd-YAG laser radiation to induce tissue to tissue adhesion, we exposed a series of separated layers of plaque and arterial wall to varying amounts of this radiation, and then quantitatively measured the strengths of the resultant adhesions.

In initial studies, we identified 2 factors that greatly facilitated laser fusion of tissue. One factor appeared to be application of firm pressure holding the layers of tissue in apposition during lasing. Sections of juxtaposed plaque and wall lased under no pressure exhibited no adhesion. The other

factor was the presence of a thin layer of blood between plaque and underlying arterial wall, which greatly improved the adhesion of these tissues. Therefore, all subsequent studies were performed with the application of pressure and with the presence of blood between the separated tissue layers.

Fresh postmortem human atheromatous aortas and iliac arteries were opened with a longitudinal incision and plaque was stripped from the underlying arterial wall. Plaque types were judged to be either fibrofatty or calcific by gross feel and appearance. The separated layers of plaque and outer arterial wall were then cut into squares of approximately 1 cm^2 each. Plaque thickness was measured with a micrometer caliper. We paired pieces of plaque and outer wall, being careful to preserve their original anatomic orientation, placed a small drop of fresh heparinized dog blood between the layers, and sandwiched the complex between 2 microscope slides held together with a spring clamp (Fig. 1).

Nd:YAG laser radiation was then directed perpendicularly toward the luminal surface of the sandwiched tissues via a 600-μ core optical fiber, the end of which was maintained at a fixed distance 1 cm from the surface of the glass slide during laser exposure. The He-Ne reference beam illuminated a spot size of approximately 2 mm in diameter, and the power output from the optical fiber was adjusted to 17 W. This peak power resulted in a nominal power density of about 500 to 600 W/cm^2 without considering reflection of unknown magnitude from the glass microscope slide and the luminal plaque surface. However, because of scattered radiation and thermal diffusion, the functional size of the tissue region heated by the laser radiation was considerably greater than the nominal 2-mm spot size of the reference beam. Indeed, the temperature of tissue at a distance of 2 mm from the edge of the reference spot plateaued at 58°C, as measured with a thermistor mounted on a 25-gauge needle (Yellow Springs Instrument Corp.) after 10 seconds of lasing. After irradiation, welded sets of tissue were stored in saline solution at 4°C before strength testing or histologic evaluation.

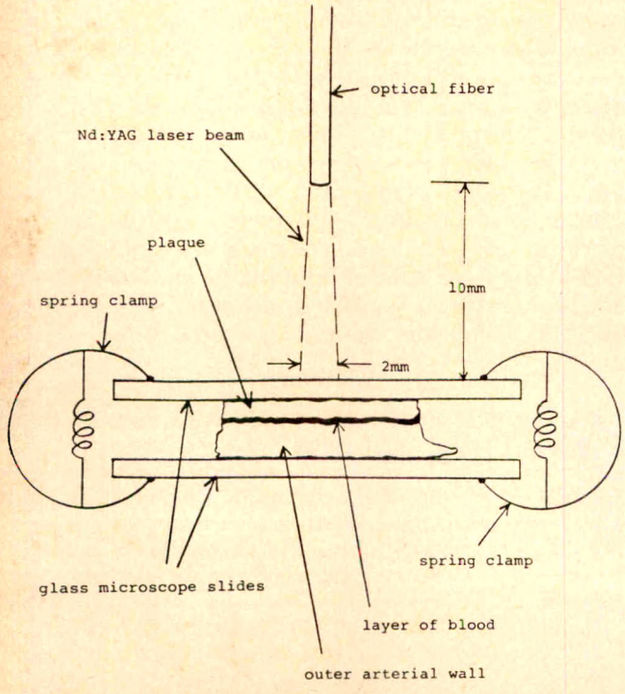

FIGURE 1. Experimental setup for laser fusion of sections of plaque and underlying arterial wall.

To quantitate the strength of the laser-induced welds, the tissues were subjected to gradually increasing loads until the welds separated. The loading was performed by cementing the adventitial surface of the artery to a stiff support with cyanoacrylate adhesive (Crazy Glue™) and suspending weights from a 4-0 silk suture sewn through the flaps of plaque on either side of the weld. The maximal weight that could be suspended from the suture was used as a measure of the strength of the weld.

Specimens for histologic evaluation were fixed in 10% formalin, embedded in plastic, and sections were stained with hematoxylin-eosin.

Segments of whole artery: The efficacy of applying intraluminal Nd-YAG laser radiation from an inflated balloon to weld separated layers of plaque and underlying arterial wall was tested in fresh, whole, postmortem human atheromatous iliac arteries cut transversely into 2-cm-long segments. For each of the 6 segments studied, the inner layer of plaque was dissected completely from the outer layer of arterial wall without cutting through either the plaque or the outer wall before laser treatment (Fig. 2, a and b).

A prototype balloon catheter was constructed from silicone-based materials that were relatively transparent to Nd-YAG laser radiation and that were unaffected by high temperatures (more than 100°C). The 600-μ core of the optical

fiber used to transmit the 1.06-μ radiation terminated within the balloon in a 5-mm-long diffusing tip that provided radially directed dispersion of the radiation around the circumference of the balloon.

Before inserting the balloon catheter into an arterial segment, fresh heparinized human blood was injected into the lumen and between the separated layers of plaque and arterial wall. The deflated balloon was then inserted into the lumen and fluid-inflated to approximately 2 atm of pressure. The diameter of the inflated balloon was 8 mm, slightly larger than the luminal diameter of the arterial segments. Laser exposure at 20 W was then performed for 18 to 40 seconds, beyond which duration the onset of tissue vaporization occurred. After laser exposure, the artery was permitted to cool for 5 to 10 seconds before deflating the balloon and removing the balloon from the arterial segment.

The segments were then sliced longitudinally and submitted to testing for weld strength in a manner identical to that described earlier.

Results

Squares of arterial wall: The strength of tissue welds for a given exposure duration depended, in part, on plaque thickness and composition (Table I). Thick, calcific plaques generally formed weaker adhesions than thin, fibrofatty plaques, but because most of the thick plaques were also calcific, we could not separate the importance of these 2 variables. Exposure duration was another important variable; weld strength was roughly proportional to lasing duration, with some welds supporting as much as 20 to 25 g (Fig. 3). Vaporization usually resulted from a lack of pressure on the tissue or from a long lasing duration, but also occurred when a plaque was hemorrhagic in appearance. The onset of vaporization was accompanied by a characteristic high-frequency sound. A thin layer of blood on the intimal surface had little or no effect on weld strength.

Histologic examination of the vessel wall segments revealed multifocal zones of adherence within the media of the treated vessel (Fig. 4). There was a generalized mild tissue coagulation throughout the vessel wall, which was most prominent in the junctional zone. Furthermore, there was prominent fat necrosis at the adventitial surface.

Segments of whole artery: Of the 6 segments tested, 3 exhibited no adhesion, 1 slight adhesion (supporting 8 g) and 2 excellent adhesion (supporting 70 g and 165 g). Two of the 3 that exhibited no adhesion were lased for less than 20 seconds. During irradiation of a segment, the arterial wall appeared to shrink at the smaller ends of the balloon and mold itself to the shape of the balloon. After exposure, the wall seemed stiff and inelastic, having a rubbery consistency. The welds formed in these whole artery segments were nonuniform about the circumference of the artery, most likely as a result of nonuniformity of radiation scatter within the prototype

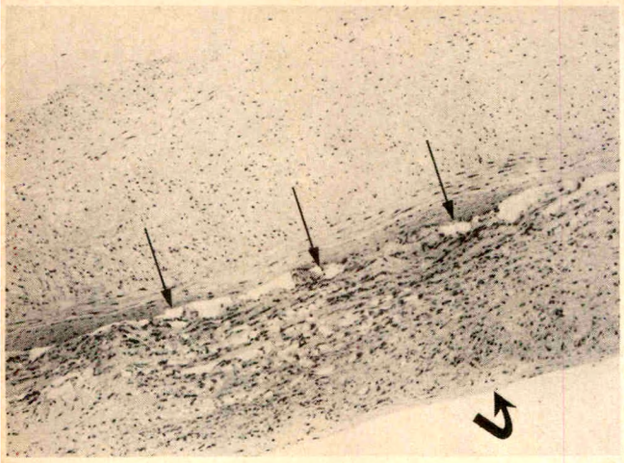

FIGURE 4. Histologic section of welded iliac artery showing zone of adhesion. The entire cross section of the artery is shown; the luminal surface is indicated by the **curved arrow** and line of weld zone is indicated by **straight arrows.** The junctional zone is within the longitudinal medial smooth muscle layer. Hematoxylin-eosin stain; magnification ×80, reduced 66%.

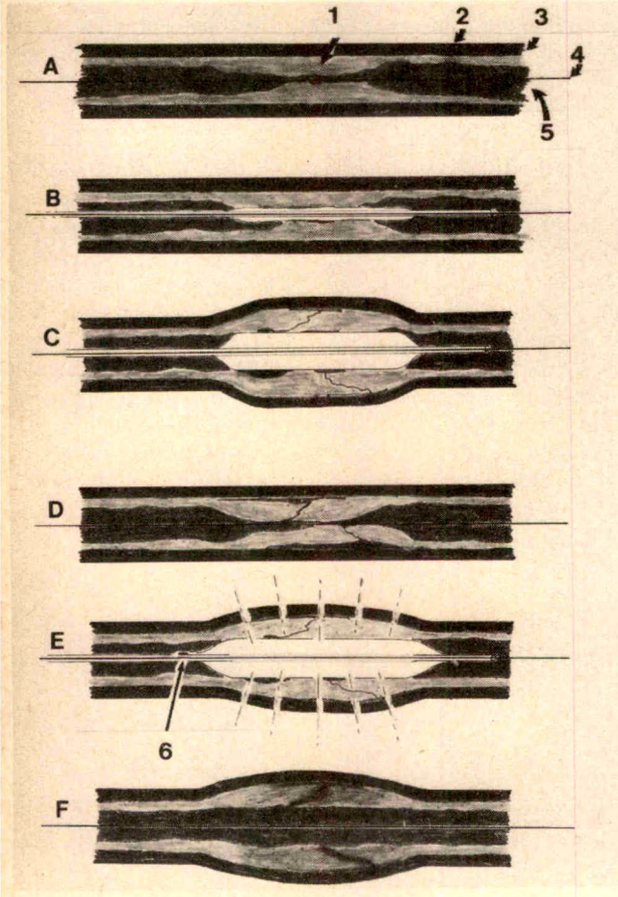

FIGURE 5. A to **C,** conventional balloon angioplasty in which a guidewire (4) is inserted into the arterial lumen (5). The balloon is threaded over the guidewire to the obstructing plaque (1) and inflated, sometimes causing dissection of the arterial wall to the media (3) or occasionally even the adventitia (2). Extensive dissection may cause abrupt reclosure (**D**). In this instance, laser balloon angioplasty (**E**) may be useful in fusing dissected layers of arterial wall, resulting in a smooth, dilated lumen (**F**). Lasing complications may be avoided by using an acoustic sensor (6) to detect the onset of tissue vaporization.

balloon. The balloon itself was unaffected by the laser radiation and there was neither adhesion between the balloon and the intimal surface nor thrombus formation at either end of the balloon.

Discussion

Although the mechanism of laser-induced tissue fusion is not clearly understood, investigators have postulated that a heat-induced shrinkage and cross-linking of tissue proteins may partially explain the phenomenon.[11] Others have shown that the arterial wall would shrink when heated, and that, in fact, the elastic resistance of the tissue actually increases with temperature.[12,13] Unrestrained, this shrinkage would lead to a reduction in the size of the luminal cross-sectional area. However, with an inflated balloon maintaining luminal size in the present study, the shrinkage had the effect of compressing the inner wall and improving adhesion of disrupted elements. By maintaining balloon inflation for 5 to 10 seconds after cessation of laser irradiation, no further tissue shrinkage occurred on balloon deflation. Furthermore, the artery showed no recoil on balloon deflation, and the luminal diameter equal to that during maximal balloon inflation was maintained.

Despite the coagulative properties of Nd-YAG laser radiation, thrombus formation within the lumen of the whole arteries was not a problem because the inflated balloon displaced blood from the luminal surface. The proximal and distal ends of the balloon, which were in direct contact with blood, were not exposed to the laser radiation, so that coagulation of blood at these locations could be avoided.

Fusion of thick, calcified plaque to the underlying wall may require a laser exposure duration that may not be markedly shorter at the power densities used herein than the exposure duration resulting in the onset of tissue vaporization. The latter, if continued, could cause vessel perforation or result in aneurysm formation.[14,15] Significant vaporization might be avoidable by terminating lasing on detection of the high frequency sound generated at the onset of vaporization (Fig. 5).

Refinements in balloon catheter and optical fiber materials and designs is needed to construct an optimal laser delivery system during balloon angioplasty. In addition, although tissue healing after laser-induced vascular anastomosis[10] and intraluminal laser-induced injury to the arterial wall[16] is excellent in experimental studies, the acute and chronic in vivo effects of Nd-YAG irradiation on the normal and atherosclerotic wall as performed in the present study must be characterized. However, these preliminary results suggest that the proposed catheterization technique is effective and implementable. If in vivo studies are similarly encouraging, laser balloon angioplasty may be useful for treating both spontaneously occurring and PTCA-induced arterial dissections. This application, coupled with the potential for an improved vessel dilatation, should result in an improved luminal geometry and may reduce the incidence of both abrupt reclosure and restenosis associated with PTCA.

Circulatory Effects of Coffee in Relation to the Pharmacokinetics of Caffeine

PAUL SMITS, MD, THEO THIEN, MD, and ALBERT van't LAAR, MD

Drinking coffee results in an increase in blood pressure (BP) after an interval of caffeine abstinence. During chronic caffeine intake this pressor response disappears and adaptation to the circulatory effects of caffeine develops. This study was designed to determine whether a pressor response to coffee occurs during chronic caffeine intake if low basal plasma caffeine levels are achieved by a period of caffeine abstinence, defined by individual plasma caffeine half-life. In 8 normotensive subjects, circulatory measurements were studied after ingestion of coffee in 2 strengths, decaffeinated coffee and hot water after a caffeine abstinence of 4.5 times individual caffeine half-life. These measurements were compared to the same protocol without intervention. Coffee of both strengths resulted in a similar increase in BP (diastolic BP ± 15%). The coffee-induced increase in forearm blood flow and plasma epinephrine levels were less pronounced. Decaffeinated coffee induced a smaller increase of diastolic BP, and after water, no changes were observed. Additionally, a negative correlation was found between the coffee-induced BP increase and basal plasma caffeine level in a group of 30 normotensive subjects ($r = -0.71$, $p < 0.001$). During chronic caffeine intake, subjects with short plasma caffeine half-life are exposed to a pressor response after drinking coffee, despite the phenomenon of adaptation.

(Am J Cardiol 1985;56:958–963)

Because caffeine and coffee are widely consumed throughout the world, a relation between coffee and blood pressure (BP) would be of clinical interest.[1,2] Recent studies have reported a positive association between BP and coffee consumption.[3,4] There is also pharmacologic evidence for a BP-increasing effect of caffeine and coffee.[5–7] The relevance of these observations to the effect of daily coffee use on BP was questioned by some investigators.[8,9] According to these studies complete adaptation or tolerance to the circulatory effects of caffeine develops during chronic caffeine use. However, in 1 study there was evidence that cardiovascular reactivity to caffeine was greater in subjects with initial caffeine levels of less than 1 mg/liter than for those with basal plasma caffeine levels of more than 1 mg/liter.[8] This means that the development of tolerance to the effects of coffee depends on prior caffeine use and on the individual pharmacokinetics of caffeine. In healthy subjects, elimination half-life ($T_{1/2}$) of plasma caffeine varies between 1.5 and 9.5 hours.[10] To determine whether coffee increases BP during chronic caffeine ingestion, the time of caffeine abstinence before the test must be related to individual pharmacokinetics of caffeine. We studied the circulatory effects of drinking coffee after a period of caffeine abstinence related to individual plasma caffeine $T_{1/2}$ in 8 normotensive subjects. Hemodynamic and humoral effects of 2 strengths of coffee, and of equal amounts of decaffeinated coffee and water of the same temperature were compared to a similar protocol without intervention. In 30 other normotensive subjects, we analyzed the relation between basal plasma caffeine level and the coffee-induced increase in BP.

Methods

Eight normotensive, healthy subjects (5 men, 3 women) gave informed consent for this study, which was approved by the hospital ethical committee. The mean age was 23.4 years (range 21 to 25), height 180.4 cm (range 169 to 201) and Quetelet index 21.5 kg/m^2 (range 17.9 to 24). All subjects were accustomed to daily coffee ingestion, and mean estimated coffee use ranged from 4 to 9 cups/day. Three men were habitual smokers and all women used oral contraceptive drugs.

The first part of the study was a pharmacokinetic analysis of all subjects. Before and after drinking 2 cups of coffee, blood

samples were drawn for determination of plasma caffeine concentration. After coffee ingestion, blood was sampled every 20 minutes for 2 hours, and afterward another 3 times distributed over about 20 hours. From these data, time of plasma peak level (Tm) was registered and the elimination caffeine $T^1/_2$ was calculated. As $T^1/_2$ and Tm do not differ within an individual after different doses of oral caffeine, a single measurement of these values was sufficient.[10]

After this pilot study every subject took part in 5 tests, which were ordered at random and separated from each other by at least 1 week. All tests had the same protocol, different only in the kind of intervention: similar amounts of regular coffee, stronger coffee, decaffeinated coffee, hot water and "no intervention." For the tests with regular, strong and decaffeinated coffee the protocol was single-blind, but as a matter of course this could not be realized for the tests with hot water and no intervention. Before all tests were performed, the subjects had to abstain from all caffeine-containing products for a period of 4.5 half-lives. At the beginning of this period 200 mg of caffeine were ingested (as tablets) to be sure that abstinence was not longer than 4.5 half-lives. The subjects were not allowed to smoke for 8 hours before the tests and a light caffeine-free breakfast was allowed between 7:30 and 8:00 AM.

All tests were performed from 8:15 to 11:15 AM with the subject in the supine position. The first 30 minutes served as an equilibration period to reach basal hemodynamic and humoral values. In this period an Arteriosonde 1225 (semiautomatic BP monitor) and a mercury strain-gauge venous occlusion plethysmograph (forearm blood flow registration) were connected to the subject's left arm. Because we only wanted to measure muscle flow, a wrist cuff was inflated during the measurements to block the skin flow of the hand. Heart rate was measured by electrocardiogram. An antecubital vein of the right arm was cannulated and blood samples were taken for determination of plasma caffeine, renin and norepinephrine concentrations just before intervention, at the individual Tm and 120 minutes after intervention. After the first 30 minutes of equilibration, systolic and diastolic BP and heart rate were measured every 5 minutes for 30 minutes. In between these measurements, 4 series of 3 forearm blood flow recordings were made and blood was sampled. Subsequently the subjects had to drink 300 ml of a beverage within 10 minutes in the supine position with the aid of a straw (except in the no-intervention test). All beverages were prepared using a coffee machine with 300 ml of water and, depending on the test, 25 g of coffee (strong coffee), 17.5 g of coffee (regular coffee), 17.5 g of decaffeinated coffee and no coffee (hot water test). Then, systolic and diastolic BPs and heart rate were recorded every 5 minutes for 2 hours, and again a series of 3 forearm blood flow registrations were made in between.The protocol of the tests is illustrated in Figure 1.

In 30 other normotensive and healthy subjects we also studied the hemodynamic effects of coffee. The same protocol as in the regular coffee test was used. For these subjects, however, the time of caffeine abstinence was arbitrary and not related to plasma caffeine $T^1/_2$. We used this group to study the relation between basal plasma caffeine levels and pressor responses to coffee. In these subjects we did not sample blood for determination of plasma catecholamines or plasma renin activity.

Plasma concentrations of caffeine were analyzed with a reversed-phase high-performance liquid chromatography method.[6] Plasma catecholamine levels were measured by a radioenzymatic assay,[11] and plasma renin activity by radioimmunoassay.[12]

Statistical analysis: Hemodynamic variables before intervention were averaged for each subject to 1 basic value, and after intervention to 1 value for every period of 20 minutes. Differences between the 20-minute-period values and the basic value were averaged for each subject, resulting in 1 mean change over the 2-hour period. In the statistical analysis these mean changes induced by strong, regular or decaffeinated coffee or hot water were compared with the results of the no-intervention test by Student *t* test for paired observations (2-sided). Humoral variables were analyzed by comparing values after intervention with basal values by the paired Wilcoxon test (2-sided). The fractional changes in the 5 tests also were compared with each other. Correlation coefficients were calculated according to Pearson. Mean arterial pressure was calculated as the sum of diastolic BP and one-third of pulse pressure, and forearm vascular resistance was calculated by dividing mean arterial pressure through forearm blood flow. Forearm vascular resistance is expressed in arbitrary units. All results are presented as mean ± standard error of the mean.

Results

The results of the preliminary pharmacokinetic measurements are shown in Figure 2. Peak plasma caffeine concentrations were reached in 4 subjects in the first, in 1 in the third, in 2 in the fourth and in 1 in the fifth 20-minute period after coffee. The mean Tm was 50 ± 12 minutes. Calculated $T^1/_2$ ranged from 2 to 8.5 hours (mean 4.2 ± 0.8). The caffeine abstinence period for the 5 tests ranged from 9 to $38^1/_4$ hours. In the pilot study the mean peak plasma caffeine level was 4.3 ± 0.6 mg/liter. Figure 2 shows that plasma caffeine levels are almost in a steady state during the tests.

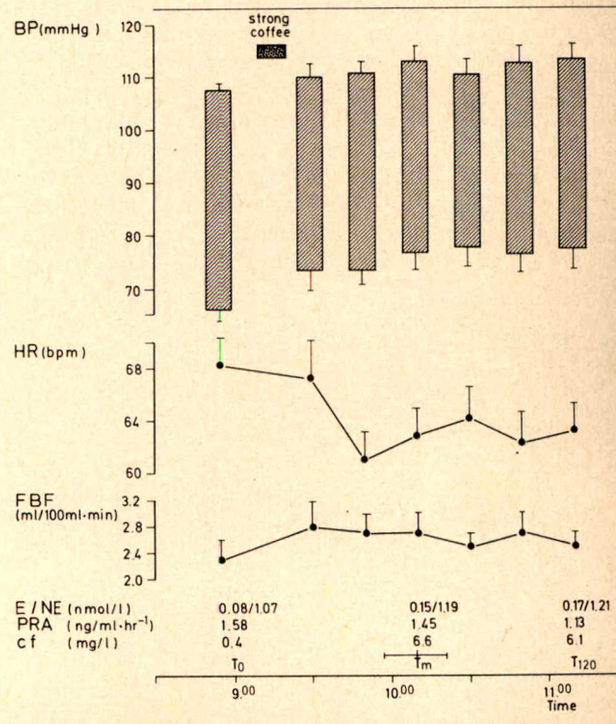

FIGURE 1. Schedule of measurements in 8 subjects after drinking strong coffee. Mean values (± standard error of the mean) of blood pressure (BP), heart rate (HR) and forearm blood flow (FBF) before and for 6 periods of 20 minutes after coffee ingestion are given. Plasma concentrations of norepinephrine, epinephrine (NE, E), renin (PRA) and caffeine (cf) were measured 3 times. Tm = time of plasma peak level.

TABLE I Basal Values of all Hemodynamic Parameters in the Five Tests

	NI	W	DC	RC	SC
Systolic blood pressure (mm Hg)	110 ± 2	111 ± 2	113 ± 2	110 ± 2	108 ± 1
Diastolic blood pressure (mm Hg)	72 ± 2	68 ± 3	67 ± 2	66 ± 3	66 ± 2
Mean arterial pressure (mm Hg)	85 ± 2	83 ± 2	82 ± 2	81 ± 2	81 ± 2
Heart rate (beats/min)	72 ± 3	73 ± 3	72 ± 3	73 ± 3	68 ± 2
Forearm blood flow (ml/100 ml·min)	2.5 ± 0.2	2.7 ± 0.3	2.7 ± 0.3	2.6 ± 0.3	2.3 ± 0.3
Forearm vascular resistance (U)	37 ± 4	34 ± 5	34 ± 4	36 ± 6	40 ± 6

All values are mean ± standard error of the mean.
DC = decaffeinated coffee; NI = no intervention; RC = regular coffee; SC = strong coffee; W = water.

In Table I all basal hemodynamic data of the 5 tests are listed, and these values revealed no statistically significant differences. Mean changes over the 2-hour period of systolic and diastolic BPs, heart rate and forearm blood flow in the 5 experimental situations are shown in Figure 3. In the regular and strong coffee tests, the systolic BP increase measured 4 ± 1 and 5 ± 2 mm Hg, respectively; these increases were significantly higher than those in the other tests. The same applied to the increases in diastolic BP of 8 ± 1 and 9 ± 1 mm Hg, respectively, and in mean arterial pressure of 7 ± 1 mm Hg in both tests. Figure 4 shows that the increase in BP was maximal in the last hour. In the regular and strong coffee tests, the percent increase in diastolic BP in the last 20-minute period was 16 ± 3% and 15 ± 4%, respectively. After ingestion of regular coffee, the individual maximal increase in mean arterial pressure ranged from 8 to 19% and after strong coffee from 8 to 15%. There was no relation between the individual increase in mean arterial pressure and the corresponding time of caffeine abstinence. After ingestion of decaffeinated coffee, a smaller increase in diastolic BP was observed, whereas drinking water did not induce any changes. In all tests a decrease in heart rate was observed, and after water, regular coffee and strong coffee, these decreases were greater than those after the no-intervention test ($p < 0.10$); they were 5 ± 1, 7 ± 2 and 5 ± 1 beats/min, respectively. Without intervention, mean heart rate decreased by 2 ± 1 beats/min (Fig. 3). There was a significant difference between the increase in forearm blood flow of 0.3 ± 0.2 ml/100 ml·min after strong coffee intake and the decrease of 0.2 ± 0.2 ml/100 ml·min during the water and decaffeinated coffee test. As a consequence mean forearm vascular resistance decreased 2.1 ± 2.8 U during the strong coffee test, which was different from the increase in forearm vascular resistance of 3.6 ± 2.1 and 3.5 ± 2.1 U after hot water and decaffeinated coffee ($p = 0.03$, $p = 0.07$).

Figure 5 shows all humoral measurements of the 5 tests. Individual basal plasma caffeine levels of these tests were all within the range of less than 0.1 to 2.0 mg/liter, independent of the time of caffeine abstinence ($n = 40$, $r = -0.25$, $p > 0.1$). After ingestion of strong and regular coffee, a significant increase in plasma caffeine levels to 6.6 ± 0.4 and 5.2 ± 0.9 mg/liter was observed, the former being significantly greater than the latter ($p < 0.005$). In the hot-water and no-intervention tests, plasma caffeine concentration showed a small but significant decrease of 0.2 mg/liter at the end of the tests;

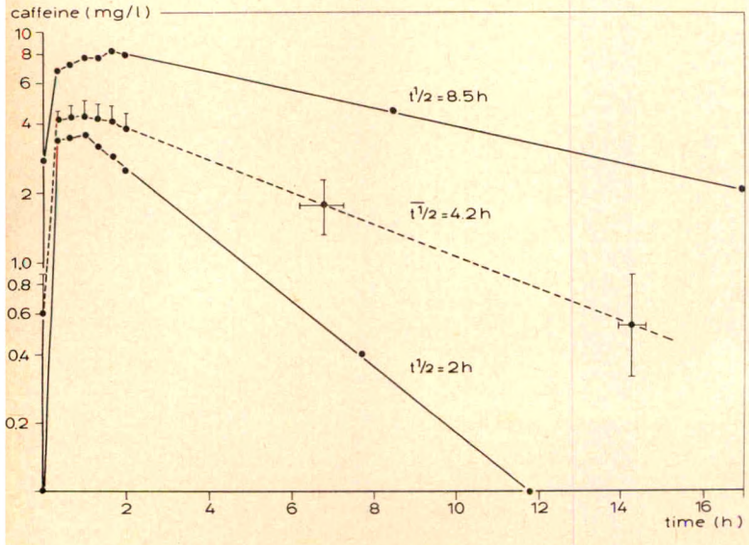

FIGURE 2. Course of plasma caffeine levels in subjects after drinking coffee. Mean results (± standard error of the mean) as well as the results of the subjects with the shortest and longest elimination half-life ($t_{1/2}$) of caffeine are given.

after decaffeinated coffee was ingested, no significant change was observed. Table II lists the mean fractional changes of plasma catecholamine levels. Changes in plasma norepinephrine levels were about the same among the 5 tests. Plasma epinephrine levels, however, increased more significantly after consumption of regular and strong coffee than after decaffeinated coffee. Plasma epinephrine levels and plasma renin activity were significantly different during all tests compared with basal values. The percent reduction of plasma renin activity after drinking decaffeinated coffee ($-17 \pm 7\%$), regular coffee ($-19 \pm 7\%$) and strong coffee ($-18 \pm 5\%$) was smaller than after drinking hot water ($-33 \pm 5\%$, $p < 0.10$). In the 4 tests in which a beverage was ingested, there was a significant correlation between the increase in plasma caffeine and the fractional increase in mean arterial pressure ($n = 32$, $r = 0.70$, $p < 0.001$). The fractional increase in plasma epinephrine weakly correlated with changes of plasma caffeine ($n = 32$, $r = 0.36$, $p < 0.05$).

Figure 6 shows the most relevant results of the second part of the study. In the 30 subjects, a strong correlation was observed between basal caffeine level and the increase in mean arterial pressure in the second hour after drinking coffee (^{10}log (caffeine) vs mean arterial pressure: $n = 30$, $r = -0.71$, $p < 0.001$). Mean increase in mean arterial pressure measured $7 \pm 1\%$ (range -1 to 24%). Because of the arbitrary time of caffeine abstinence, there was also a large range of basal plasma caffeine levels (less than 0.1 to 6.3 mg/liter, mean 1.0 ± 0.3).

Discussion

Under experimental conditions there is clear evidence for a BP-increasing effect of caffeine,[5–7,13,14] but during chronic ingestion of caffeine no cardiovascular response to caffeine or coffee occurred.[8,9] In 1968, Colton et al[15] suggested that this tolerance could partly ex-

plain contradictory observations reported with respect to the circulatory effects of caffeine. The evident disparity between the acute effects of caffeine and the results of epidemiologic studies, which show no association between coffee and coronary heart disease,[16–18] also has been explained by the phenomenon of tolerance.[8]

In this study we could affirm the presumption that BP increase after consumption of coffee depends on basal plasma caffeine concentration (Fig. 6). Further, the problem has been evaluated from another point of view by testing the hypothesis, that a significant BP increase will occur when abstinence of caffeine is long enough to reach low basal plasma caffeine levels. In this study we used a caffeine abstinence of 4.5 half-lives, and such periods of abstinence are likely to occur in daily life. The range of half-lives from 2 to 8.5 hours in our subjects is in close agreement with other observations,[10] and this wide range is brought about by several exogenic influences,[19,20–22] as well as by genetically determined interindividual differences.[23] Despite a significant difference between the increase in plasma caffeine levels after ingestion of regular and strong coffee, the responses of BP were similar (Fig. 4). These results agree with the observation of a flat dose-response curve with respect to the BP-increasing effect of drinking 2 to 8 cups of coffee.[24] The observed BP increase after coffee ingestion did not show any correlation with the duration of caffeine abstinence. Consequently, we conclude that drinking coffee leads to an increase in BP after caffeine abstinence for 4.5 half-lives. In a previous study, plasma caffeine levels were measured in 600 consecutive patients; in about 50% of this group, plasma caffeine

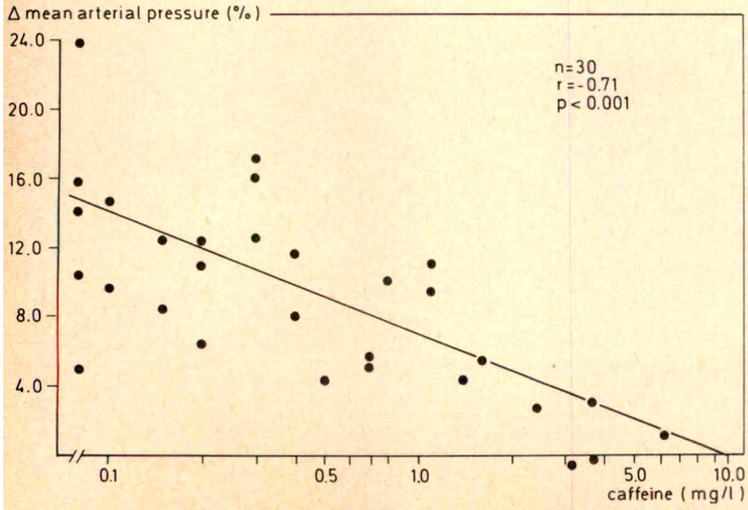

FIGURE 6. The relation between basal plasma caffeine concentration and the fractional increase in mean arterial pressure in the second hour after consumption of coffee in 30 normotensive subjects. (Δ mean arterial pressure vs ^{10}log [caffeine]).

concentration was less than 2.0 mg/liter.[25] This indicates that drinking coffee may induce an increase in BP in daily life in a considerable proportion of the population. Drinking decaffeinated coffee induced only a small increase in diastolic BP, an observation that agrees with reported data.[26]

In another study, stronger BP increases are reported after a comparable load of coffee drinking.[6] However, in that study caffeine abstinence was longer, also reflected by a lower mean basal plasma caffeine of 0.3 mg/liter. Probably, the lower BP response to coffee in this study can be traced to partial tolerance, which would disappear after longer caffeine abstinence. The complete tolerance in Robertson's study,[8] even after 15 hours of caffeine abstinence, can be explained by the extremely long mean $T^1/_2$ (10 hours) of his subjects, resulting in a mean basal plasma caffeine of 2.3 mg/liter. Ammon et al[9] also observed complete tolerance to coffee, but no plasma caffeine data were available.

Epidemiologic studies have related mean coffee consumption to BP. Because of the results of this study, we believe a more valid conclusion could be drawn if the pharmacokinetics of caffeine were taken into consideration. Additionally, epidemiologists always correct for cigarette smoking because smoking is an independent risk factor in coronary heart disease and because coffee consumption and cigarette smoking are strongly related habits.[16] Because mean $T^1/_2$ of caffeine is shorter in people who smoke,[19] our results indicate that such a correction could lead to underestimation of the relation between BP or coronary heart disease and coffee.

Decreases in heart rate did not reveal clear significant differences between the 5 tests and, therefore, an additional effect of caffeine on the decrease in heart rate could not be proved with these observations, in contrast to other reports.[5,26] The changes in forearm blood flow and forearm vascular resistance illustrate that drinking strong coffee induces a slight vasodilation in the forearm muscle when compared with beverages containing no or a very small amount of caffeine. These data are not conclusive with respect to the effect of coffee on total peripheral resistance, because caffeine could induce opposite effects in blood vessels of other organ systems.

Changes of plasma epinephrine after consumption of coffee were less striking than in former reports.[6,26] This also may be explained by partial tolerance to the effects of coffee. The decrease in plasma renin activity in all tests, including the no-intervention test, suggests that this could be the result of the circadian rhythm of plasma renin activity, because all tests were performed in the morning.[27]

From this study we conclude that drinking coffee results in an increase in BP and a possible vasodilation in forearm muscle. Plasma epinephrine levels tend to increase after coffee, whereas plasma norepinephrine and renin activity do not change. There are no differences when drinking regular or stronger coffee. Drinking water does not result in circulatory changes, whereas drinking decaffeinated coffee induces a small increase in diastolic BP when compared with no intervention. Relevant hemodynamic changes with coffee already occur after caffeine abstinence of 4.5 half-lives. In normotensive subjects there is a strong negative correlation between the coffee-induced BP increase and basal plasma caffeine concentration. The $T^1/_2$ of caffeine shows a large variation, and subjects with short $T^1/_2$ are definitely exposed to pressor responses to coffee, depending on their daily intake.

Acknowledgment: We gratefully acknowledge the technical assistance of Miekie Thissen Jansen, Ita Baars and Jacque Willemsen, who performed all plasma renin activity assays and determinations of plasma caffeine and catecholamines. The preparation of this manuscript by Ineke ten Have was greatly appreciated.

Beta-Adrenergic Stimulation Reverses Postischemic Myocardial Dysfunction Without Producing Subsequent Functional Deterioration

ROBERTO BOLLI, MD, WEI-XI ZHU, MD, MARY LEE MYERS, MD, CRAIG J. HARTLEY, PhD, and ROBERT ROBERTS, MD

The prolonged myocardial dysfunction observed after reversible ischemia (stunned myocardium) has been postulated to result from an inability of the myocytes to replenish ATP stores. Accordingly, one would expect inotropic stimulation to result in minimal increase in contractile function, or possibly even further deterioration. To test this hypothesis, studies were performed in open-chest dogs undergoing a 15-minute occlusion of the left anterior descending coronary artery (LAD) followed by 4 hours of reperfusion. Systolic wall thickening, an index of regional myocardial function, was measured in the LAD-dependent territory with ultrasonic crystals. Thickening fraction was 20.8 ± 3.0% (mean ± standard error of the mean) under baseline conditions, decreased to −18.6 ± 1.6% during LAD occlusion, and was still severely depressed after 3 hours of reperfusion (2.6 ± 3.4%). Thickening fraction remained stable between 3 and 4 hours of reperfusion in 5 untreated control dogs. In 9 treated dogs, isoproterenol (0.1 μg/kg/min intravenously for 30 minutes starting 3 hours after reperfusion) increased thickening fraction to values (24.8 ± 4.5%) that were similar to those at baseline. Thirty minutes after discontinuation of isoproterenol administration, thickening fraction had returned to pre-isoproterenol levels. Thus, reperfused, severely depressed myocardium responds dramatically to β-adrenergic stimulation without subsequent adverse effects on function in the short-term. These findings imply that the stunned myocardium can generate ATP, and therefore do not support the view that an inability to replenish ATP stores is the cause of postischemic dysfunction. More important, this study suggests that postischemic dysfunction in humans may be effectively reversed with inotropic therapy without short-term deleterious sequelae.

(Am J Cardiol 1985;56:964–968)

Myocardial reperfusion after a reversible ischemic insult is associated with prolonged contractile dysfunction (stunned myocardium).[1–3] Despite considerable investigative efforts, the mechanism for this phenomenon is unknown. Recent studies show that myocardial ATP levels are depressed after reperfusion and recover in parallel with contractile function.[2,4–6] Thus, the hypothesis has been advanced[2,3,5] that postischemic dysfunction may be the result of an inability of the myocardium to generate enough high-energy phosphates to sustain contractile function, possibly because of loss of adenine nucleotide precursors.[3,7]

Insights into this problem may be gained by assessing the effect of inotropic stimulation on reperfused, depressed myocardium. If, in fact, ATP stores in stunned myocardium cannot be repleted, inotropic stimuli would be expected to produce little or no increase in contractility or even further deterioration. A marked improvement in mechanical function, in contrast, would imply preserved ability to generate ATP. These results would have clinical implications, because it is unclear whether inotropic therapy can precipitate deleterious effects in patients with postischemic dysfunction. Accordingly, in the present study we evaluated the response of reperfused, depressed myocardium to

inotropic stimulation by the β-adrenergic agonist isoproterenol. We used a well characterized[2–4] open-chest canine model in which severe myocardial dysfunction was induced by 15 minutes of coronary artery occlusion followed by reperfusion.

Methods

Experimental preparation: Mongrel dogs of either sex that weighed 15 to 30 kg were anesthetized with sodium pentobarbital (30 mg/kg intravenously [i.v.]), intubated and ventilated with room air. The chest was opened through the left fifth intercostal space and the heart was suspended in a pericardial cradle. The left anterior descending coronary artery (LAD) was isolated from the surrounding tissue and encircled by a snare just distal to the first major diagonal branch.[8] A Doppler ultrasonic flow probe was placed around the artery distal to the site of occlusion. A polyethylene catheter was inserted through the left carotid artery into the aorta and was connected to a Statham P23Db pressure transducer. A high-fidelity micromanometer (Konigsberg P-7) was inserted into the left ventricular (LV) cavity through a stab incision in the apex. The first derivative of LV pressure (dP/dt) was obtained by electronic differentiation. To measure regional LV wall thickening in treated dogs, a pair of miniature (2 mm in diameter) ultrasonic crystals was positioned in the anterior LV wall in the region to be rendered ischemic. One crystal was inserted at an angle of 45° through the wall into the subendocardium and the other crystal was sutured to the epicardial surface at a site where the ultrasonic transit time was shortest.[9] Wall thickening in control dogs was measured with a 10-MHz pulsed Doppler ultrasonic crystal sutured to the epicardial surface. Theoretical and experimental validation of this probe has been reported.[10,11] Aortic pressure, LV pressure, LV dP/dt, LAD blood flow velocity, LV wall thickness and lead II of the electrocardiogram were recorded continuously throughout the study on an 8-channel, direct-writing oscillograph (Gould Brush, system 200).

Experimental protocol: The LAD was occluded with a hydraulic balloon occluder for 15 minutes and then reperfused for 4 hours. Beginning 3 hours after reperfusion, 9 dogs received a continuous infusion of isoproterenol (0.1 μg/kg/min i.v.) for 30 minutes, whereas 5 control dogs did not receive any treatment. Hemodynamic variables and LV wall thickness were measured before and during LAD occlusion, 1, 2 and 3 hours after reperfusion, at 10 and 30 minutes of isoproterenol infusion, and 30 minutes after cessation of infusion (i.e., 4 hours after reperfusion). Dogs were then killed with KCl (10 mEq i.v.). The heart was excised and sectioned from apex to base into 5 to 6 slices, which were incubated for 20 minutes in 1% triphenyl tetrazolium chloride (TTC) solution at 37°C[12] to verify the absence of infarction.

Measurement of wall thickening: In treated dogs, which were instrumented with 2 transit-time crystals, end-diastolic and end-systolic wall thicknesses were measured at the rapid upstroke of LV pressure and at peak negative LV dP/dt, respectively.[13] Percent systolic wall thickening (%WT) was calculated from the formula[14] (ESWT–EDWT)/EDWT × 100, where ESWT = end-systolic wall thickness and EDWT = end-diastolic wall thickness. In control dogs, which were instrumented with Doppler thickening crystals, %WT was calculated from the formula (ST/EDT) × 100, where ST = systolic increase in wall thickness and EDT = end-diastolic thickness estimated from the sample volume depth.[10] Percent systolic wall thickening measured by the Doppler probe correlates closely with that determined by the 2-crystal transit-time method over a wide range of values.[10,11] Measurements from at least 5 beats were averaged at each time point.

Values are mean ± standard error of the mean.
LV = left ventricular.

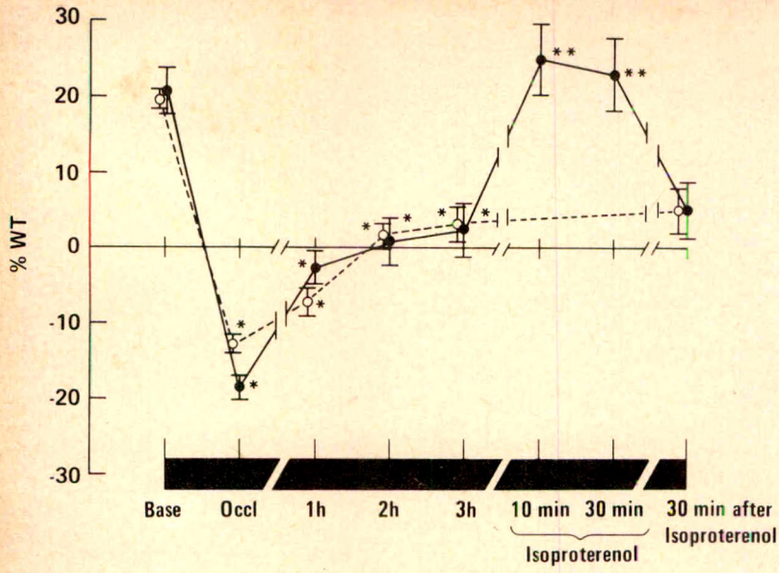

FIGURE 1. Percent systolic wall thickening (% WT) under baseline conditions (Base), during coronary occlusion (Occl), and at selected times after reperfusion. **Solid circles** with **continuous line** represent the treated group, which received isoproterenol between 3 and 3.5 hours of reperfusion; **open circles** with **dashed line** represent the control group. Wall thickening was still markedly depressed at 3 hours of reperfusion in both groups, but increased strikingly in response to isoproterenol, attaining levels slightly higher than those observed under baseline conditions, *p <0.001 vs baseline; **p <0.01 vs 3 hours.

Statistical analysis: All values are reported as mean ± standard error of the mean. Analysis of variance was used to test the differences in repeated measurements from the same dogs. If the F test showed an overall difference, comparisons between 2 time points were performed by the 2-tailed Student *t* test for paired data and the resulting p values were adjusted by Bonferroni's method.[15]

Results

Of the 18 dogs initially instrumented, 1 dog died of ventricular fibrillation during occlusion and 3 dogs died after reperfusion. The results from the remaining 14 dogs (5 control and 9 treated) form the basis of this report. TTC staining showed no evidence of irreversible damage in any of these dogs.

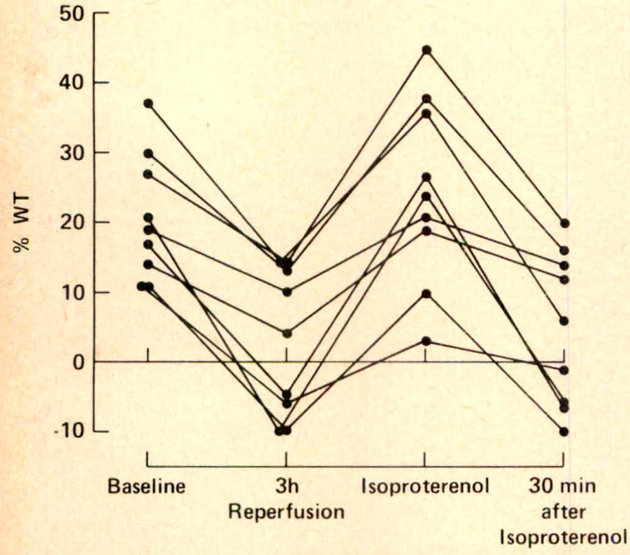

FIGURE 2. Effect of isoproterenol on percent systolic wall thickening (% WT) in individual dogs. Wall thickening values under baseline conditions, before isoproterenol (3 hours of reperfusion), 10 minutes after the start of isoproterenol infusion, and 30 minutes after cessation of infusion are shown. Isoproterenol consistently improved regional function in all dogs, including those exhibiting dyskinesia, and restored wall thickening to baseline values or above in all but 1 dog.

Systemic hemodynamics: Heart rate, mean aortic pressure and peak positive LV dP/dt values are listed in Table I. Three hours after LAD reperfusion, systemic hemodynamic values were similar to values at baseline. In the treated group, isoproterenol significantly increased heart rate and LV dP/dt ($p < 0.001$), and tended to lower aortic pressure ($p < 0.10$). These effects were no longer discernible 30 minutes after discontinuation of isoproterenol. Hemodynamic variables remained stable between 3 and 4 hours in the control group.

Regional function: In both groups, end-diastolic wall thickness decreased during LAD occlusion ($p < 0.01$), but returned to values similar to baseline after 1 hour of reperfusion (Table I). Isoproterenol produced an insignificant increase in end-diastolic wall thickness (Table I).

During LAD occlusion, systolic wall thickening was replaced by paradoxical holosystolic thinning in all dogs. After reperfusion, wall thickening remained severely depressed and at 3 hours averaged only 13.6% of the preocclusion value in the control and 12.3% in the treated group (Fig. 1). In the treated group, isoproterenol produced a dramatic increase in wall thickening, from 2.6 ± 3.4% to 24.8 ± 4.5% at 10 minutes and 23.0 ± 4.9% at 30 minutes of infusion ($p < 0.001$), values that were slightly higher than those recorded before LAD occlusion (Fig. 1). The increase was consistently observed in all dogs (Fig. 2). In the 4 dogs that still had paradoxical systolic thinning at 3 hours of reperfusion, isoproterenol induced resumption of active systolic thickening (Fig. 2). The β-adrenergic agonist restored regional contractile function to baseline levels or above in all but 1 dog (Fig. 2). An original representative recording from 1 dog is shown in Figure 3. Thirty minutes after cessation of isoproterenol infusion, wall thickening had returned to levels similar to those before infusion (Fig. 1 and 2). No significant change in wall thickening was observed between 3 and 4 hours of reperfusion in the 5 control dogs (Fig. 1).

Discussion

This study shows that reperfused, severely depressed myocardium possesses considerable functional reserve. Isoproterenol reversed postischemic dysfunction and restored wall thickening to preocclusion baseline levels (although not to the higher levels that would be expected with β-adrenergic stimulation under normal conditions). Moreover, our data show that even intense inotropic stimulation of stunned myocardium does not result in early functional deterioration after the inotropic agent is discontinued.

Our results are in agreement with those of a previous study by Mercier et al[16] showing that the administration of dopamine for 10 minutes improves the contractile function of reperfused, depressed myocardium. Mercier et al assessed segmental myocardial shortening, whereas we measured LV wall thickening. The latter method may more accurately reflect transmural myocardial function than the segment-length method because it is not affected by the variation in fiber orientation in the different layers of the LV wall.[17] Mercier et al showed that the contractile function of stunned myocardium can be greatly enhanced, but the 10-minute stimulation period may have been too short to precipitate potential deleterious sequelae. We thus extended the period of inotropic stimulation to 30 minutes. Furthermore, in order to produce intense myocardial stress, we administered large doses of isoproterenol, an extremely potent inotropic agent. It is unlikely that afterload reduction secondary to the vasodilator effects of isoproterenol contributed significantly to the enhanced contractility of stunned myocardium, because the drug produced only modest reductions in mean (from 111 ± 6 to 98 ± 3 mm Hg) and systolic (from 131 ± 6 to 126 ± 6 mm Hg) arterial pressure; furthermore, there was no significant correlation between the inotropic and hypotensive effects of isoproterenol.

Our transmural measurements of myocardial thickening do not provide information regarding the relative responses of the inner and outer layers of the LV wall to isoproterenol. Theoretically, such responses may differ. Coronary occlusion in the dog results in nonuniform transmural ischemia, with more severe flow reductions in the subendocardial than in the subepicardial layers. Recent studies from this laboratory[18] indicate that recovery of contractile function after a 15-minute coronary occlusion followed by reperfusion is also nonuniform across the LV wall, occurring more slowly in the subendocardium than in the subepicardium. Further investigations are necessary to determine whether the increased transmural myocardial thickening that is observed with inotropic stimulation reflects improved contractile performance in all layers or primarily in the less severely injured subepicardial layers.

The present study has important implications with regard to the mechanism of postischemic dysfunction. Several recent investigations[2,4–6] indicate that postischemic dysfunction is associated with myocardial ATP depletion, suggesting that the 2 phenomena may be causally related. During ischemia ATP is degraded to metabolites such as adenosine, hypoxanthine and inosine, which readily diffuse across cell membranes and are therefore washed out of the myocardium at the time of reperfusion.[3,7] Resynthesis of ATP can occur through either a slow *de novo* pathway or a faster "salvage" pathway, which involves production of adenine nucleotides from adenosine, hypoxanthine and inosine.[5] The loss of these precursors from the reperfused myocardium limits the latter pathway and is believed to account, in part, for the prolonged ATP depletion observed after reversible ischemia.[2,3,5]

If resynthesis of ATP in stunned myocardium were inherently limited, one would expect little or no response to stress, or possibly even a deterioration as a result of rapid utilization of the remaining high-energy phosphates. The striking, sustained increase in contractility observed in the present study during isoproterenol infusion and the absence of deleterious sequelae, however, clearly indicate that even severely depressed myocardium is capable of substantial ATP production, at least sufficient to support return of function to baseline levels. Hence, impaired resynthesis of ATP is not, in itself, the primary factor responsible for postischemic dysfunction. Further evidence corroborating this conclusion is provided by the finding that manipulations that attenuate ATP depletion after reversible ischemia do not result in functional improvement,[19,20] and that the severity of postischemic dysfunction does not correlate with myocardial ATP levels.[21] Recent studies from this laboratory suggest that an alternative mechanism for postischemic dysfunction may be the generation of oxygen free radicals during ischemia or reperfusion.[22] Among their many deleterious effects, these toxic oxygen metabolites cause damage to the sarcoplasmic reticulum, which may result in excitation-contraction uncoupling.[23]

Our data may have implications for numerous clinical settings in which the myocardium is exposed to transient ischemia, including acute myocardial infarction with early reperfusion (either spontaneous or induced by thrombolytic therapy), unstable or variant angina, open-heart surgery with cardioplegic arrest and cardiac transplantation. The presence of stunned myocardium

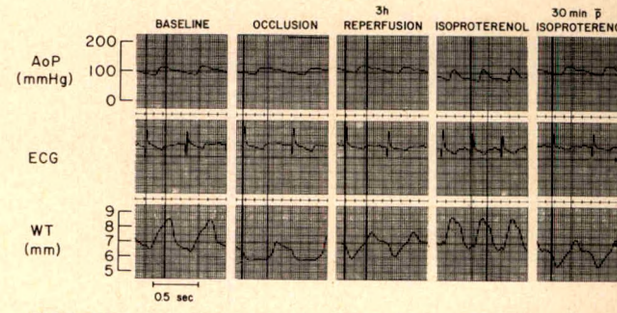

FIGURE 3. Original recordings from a dog in the treated group. Systolic wall thickening (WT) present under baseline conditions was replaced by holosystolic thinning during left anterior descending coronary artery occlusion with minimal recovery 3 hours after reperfusion. Isoproterenol markedly increased function, with resumption of active systolic thickening. Thirty minutes after isoproterenol was discontinued (30 min $\bar{p}$ isoproterenol), wall thickening was similar to that observed before isoproterenol. AoP = aortic pressure; ECG = electrocardiogram. **Vertical lines** indicate beginning and end of systole.

in these settings is suggested by several recent observations,[3,24–26] and may be an important factor precipitating LV failure. If applicable to man, our results indicate that postischemic dysfunction can be effectively reversed with inotropic therapy without short-term deleterious sequelae. Further studies, however, are needed to determine whether such inotropic stimulation adversely affects the recovery of stunned myocardium in the long term.

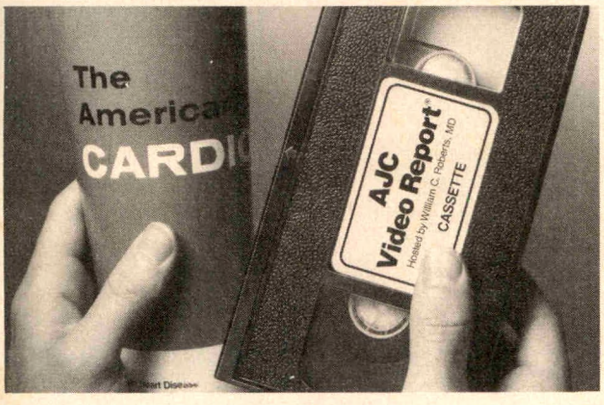
The American Journal of Cardiology does more than just print the best in authoritative articles on cardiovascular treatment. Now it puts them on videotape.

Hosted by Editor-in-Chief William C. Roberts, MD, *AJC Video Report* will feature lively, highly-visualized discussions with noted cardiovascular specialists and authors of the most important articles appearing each month in *The American Journal of Cardiology.* And it will extend the utility of the articles by exploring their application in clinical practice.

Each of the 45 minute videocassettes will feature a special guest panelist as well as the guest authors discussing:

• Coronary Heart Disease • Arrhythmias and Conduction Disturbances • Systemic Hypertension • Congestive Heart Failure • Valvular Heart Disease • Cardiomyopathy • Congenital Heart Disease • Cardiovascular Pharmacology and • Experimental Studies

AJC Video Report will be produced on a regular monthly basis starting January, 1986.



TO RECEIVE every copy of AJC Video Report—at the special introductory subscription price of $395* for 12 cassettes—complete this coupon and send it to: Joyce Sturges, *AJC Video Report,* The Yorke Medical Group, 875 Third Avenue, New York, N.Y. 10022. Or call (212) 605-9549.

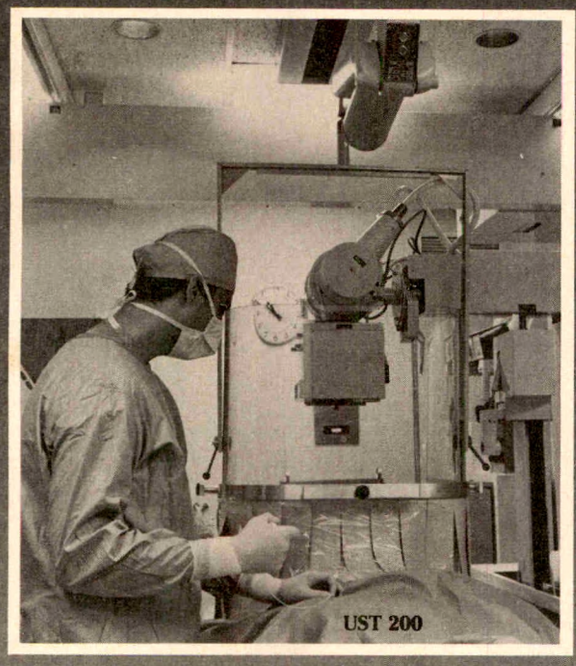
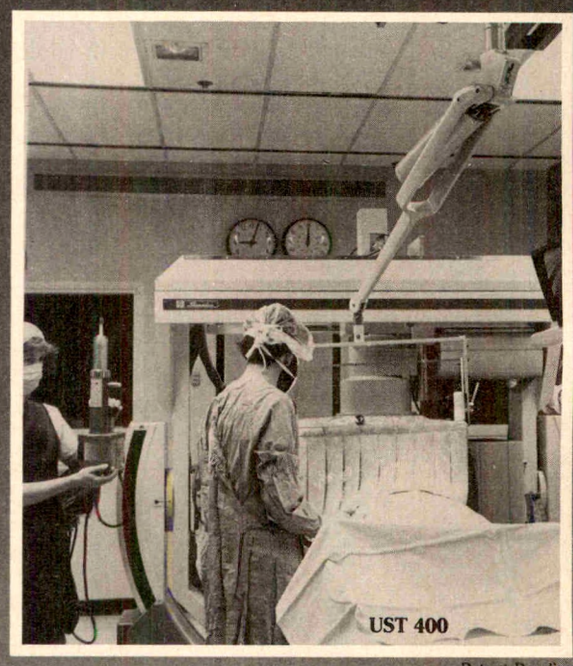
A Radiation Protective Shield for Interventional Radiology

"Provides protection from patient scatter during lengthy fluoroscopic procedures without interfering with the performance of the examination"





Patent Pending

The growing concern for radiation protection during modern theraputic fluoroscopic techniques for embolizations, abscess drainage, biliary drainage, cardiac catheterizations and other lengthy procedures has created a universal need for protective devices to shield harmful patient scatter.

The UST Interventional Shield, which is positioned close to the x-ray source, effectively reduces scatter radiation to less than 0.1 mr/hr, offering the maximum protection to the eyes, thyroid and complete upper torso of staff employees performing the procedure, while allowing total freedom of movement around the work area.

FEATURES:

- Lead acrylic patient observation panel (0.5mm to 1.0mm lead equivalency)
- Double split lead/vinyl patient forming curtain (1.0mm total lead equivalency) with disposable sterilized clear plastic sleeves
- Detachable aluminum positioning handles for autoclave use
- Dual pivotal locking devices
- Counter balanced ceiling suspension system and track assembly with 202 centimeters of horizontal travel

Also available for "C" and "U" - ARM type apparatus

Myocardial Kinetics of Thallium-201 After Stress in Normal and Perfusion-Reduced Canine Myocardium

ROBERT D. OKADA, MD

Despite the emerging use of quantitative computer programs for assessing myocardial thallium uptake and clearance after exercise, little is known about the kinetics of thallium after exercise stress. Accordingly, 11 mongrel dogs with experimental left anterior descending coronary stenoses were given thallium during norepinephrine infusion to simulate exercise. The infusion was discontinued and thallium activity was monitored regionally using miniature radiation detectors for 3 hours. Heart rate, arterial pressure and double product all increased significantly during norepinephrine infusion. The mean fractional myocardial thallium clearance was lower (0.47 ± 0.03 [± standard error of the mean]) for the stenosis zone than for the no-stenosis zone (0.57 ± 0.03) ($p < 0.0001$). The stress blood flow ratio (stenosis/no-stenosis zone = 0.27 ± 0.06) was significantly lower than the final thallium activity ratio (0.68 ± 0.07) ($p < 0.001$), consistent with thallium redistribution occurring over the 3-hour period. Myocardial thallium activity in the stenosis zone peaked in a mean of 2.2 minutes, then washed out biexponentially with a final decay constant of 0.0035 ± 0.0005 min^{-1}. Myocardial thallium activity in the no-stenosis zone peaked within 1 minute in all dogs, then washed out biexponentially, with a final decay constant of 0.0043 ± 0.0003 ($p < 0.001$ compared with stenosis zone). In conclusion, fractional clearance of thallium can differentiate myocardium distal to a coronary artery stenosis from that supplied by a normal coronary vessel.

(Am J Cardiol 1985;56:969–973)

Thallium-201 imaging in conjunction with exercise electrocardiography is widely used for the diagnosis of coronary artery disease. Studies have shown an improved diagnostic accuracy for the thallium study compared with exercise electrocardiography alone.[1] Thallium redistribution—the resolution on delayed images of a defect observed on initial post-stress images—has been used as an indication of stress-induced ischemia as opposed to scar.[2] Quantitative computer techniques were recently described for analyzing the initial uptake and subsequent clearance of thallium from the myocardium.[3–11] Therefore, it is important to understand the kinetics of thallium uptake and clearance from ischemic and normal myocardium after thallium administration during stress. Normal myocardial thallium clearance rates are difficult to determine from patient studies, because background can be difficult to subtract accurately. Therefore, miniature implantable cadmium telluride radiation detectors were developed.[12] These detectors permit continuous monitoring of thallium activity in experimental models without the need for background correction. In the present study these miniature radiation detectors were used to study thallium kinetics after stress in myocardium supplied by stenotic and normal coronary arteries.

Methods

Canine preparation: Eleven adult mongrel dogs (mean weight 20 kg, range 17 to 23) were studied. The canine preparation has been reported.[13] Electrocardiographic lead II and pressures (P23Db transducers, Gould Inc.) were monitored continuously throughout the experiment and recorded on paper with a Hewlett-Packard recorder (model 7788A). Samples of arterial blood were drawn frequently to assess pH, P_{O_2} and P_{CO_2}. Appropriate adjustments were made to maintain values in the physiologic range (pH 7.35 to 7.45 and P_{CO_2} 30 to 40 mm Hg). Arterial P_{O_2} was maintained between 100 and 150 mm Hg throughout the experiment.

A miniature cadmium telluride radiation detector attached to a modified arterial clamp was inserted through the left ventricular apex, positioned against the posterior wall endocardium, and used for on-line monitoring of thallium-201 activity distal to the balloon occluder (Fig. 1). A similar detector was positioned against the left ventricular anterior wall endocardium. The endocardial position for the detectors was chosen so that monitored activity would be less affected by activity from the opposite wall and the blood pool. The anterior wall detector was positioned to face through the open thoracotomy, thereby further reducing background activity. A lead sheet (1/8 inch) was placed between the posterior wall and the pericardium to further reduce background activity from this probe. The physical characteristics of the cadmium telluride probes have been reported.[6] The probes were connected via preamplifiers to a multichannel analyzer (Series 30, Canberra Industries), which allowed continuous moni-

toring and display of thallium-201 activity in the 2 regions. Sonomicrometer transducer crystals (3 mm in diameter) were attached to both arms of each arterial clamp and connected to a sonomicrometer (model NI-202-4R, Norland Instruments) to determine wall thickness.[14]

Experimental protocol (Fig. 2): Using the electromagnetic flow probes as guides, the balloon occluder was inflated to create resting flow ratios (left anterior descending/left circumflex zones) ranging from 0.95 to 0.40 for the 11 dogs. After a 30-minute stabilization period, baseline hemodynamic values were recorded. These measurements included heart rate, cardiac output, sonomicrometer-determined wall thickness, and arterial, left atrial, pulmonary arterial and distal left anterior descending coronary arterial pressures. Regional myocardial blood flow was determined by the administration of 4.5 million tin-113-labeled, 15- to 17-μ microspheres (30 μCi total activity) into the left atrium. Arterial reference blood samples were collected for 2 minutes after the microsphere injection.

An infusion of norepinephrine was then started into the right atrium (8 mg in 250 ml of saline solution). The infusion rate was increased, aiming for a target arterial systolic blood pressure of 200 mm Hg, because this level is the maximal response in untethered dogs.[15] The infusion was continued for 4 minutes. Thallium-201, 1.0 mCi, was then administered into the second venous catheter. Simultaneously, regional myocardial blood flow was determined by administration of 4.5 million niobium-95-labeled, 15- to 17-μ microspheres (30 μCi total activity) into the left atrium. Arterial reference blood samples were collected for 2 minutes. To measure blood thallium activity over time, 1-ml arterial blood samples were collected at 2, 4, 6, 8, 10, 20, 30, 60, 90, 120, 180 and 240 min-

utes after thallium injection. One minute after the thallium injection, the norepinephrine infusion was stopped. Miniature radiation detector probe counts were then monitored continuously in 1-minute intervals over the following 180 minutes. Heart rate, cardiac output, sonomicrometer-determined wall thickness, and arterial, left atrial, pulmonary arterial and distal left anterior descending coronary arterial pressures were determined frequently. At the end of the 180-minute period, regional myocardial blood flow was determined a last time by administration of scandium-46-labeled microspheres into the left atrium. The dog was then killed and myocardial and blood samples were counted in a well counter as previously reported.[13]

Data analysis: The 3-hour fractional myocardial thallium clearance was calculated from the probe activities at the beginning (first minute values) and end of the 180-minute monitoring period. The 3-hour fractional myocardial thallium clearance for the anterior wall (balloon stenosis zone) was compared to that for the posterior wall (no balloon stenosis zone). The stress regional myocardial blood flow ratio (stenosis/no stenosis) as determined by microspheres was compared with the final thallium activity ratio as determined in the well counter. A greater final thallium ratio than stress blood flow ratio was considered evidence of thallium redistribution. Myocardial and blood time-activity curves were also analyzed using a computer-assisted, nonlinear, least-squares estimation of the decay constant λ (min^{-1}). Curves were best fit to either a monoexponential, biexponential or triexponential fit. In the case of a triexponential fit, λ_1 was the initial decay constant, λ_2 the intermediate decay constant and λ_3 the final decay constant.

Values are mean ± standard error of the mean. Differences between rest and stress hemodynamic values and between stenosis and no stenosis myocardial zones were analyzed by a paired *t* test.

Results

Hemodynamic data (Table I): Heart rate, mean arterial pressure, and double product all increased significantly during norepinephrine infusion (all $p < 0.0001$). Heart rate, arterial pressure and double product were not significantly different from baseline values at the end of the study. Cardiac output and mean left atrial, pulmonary arterial and distal left anterior descending coronary arterial pressures also increased significantly during norepinephrine stress (all $p < 0.0001$) and were unchanged from baseline values at the end of the study. Sonomicrometer-determined mean myocardial wall thickness did not change during the experiment.

Regional myocardial blood flow was significantly lower in the stenosis zone (0.80 ± 0.13 ml/min/g) than in the no-stenosis zone (1.33 ± 0.13 ml/min/g) at rest ($p < 0.001$). Blood flow in the stenosis zone increased, but not significantly, during norepinephrine infusion. Flow in the no-stenosis zone increased significantly, to 5.33 ± 0.74 ml/min/g, during norepinephrine infusion ($p < 0.0001$).

Thallium clearance data: The no-stenosis and stenosis zone myocardial thallium clearance curves for 1 dog (dog 5) are shown in Figure 3. Fractional myocardial thallium clearance was 0.61 for the no-stenosis

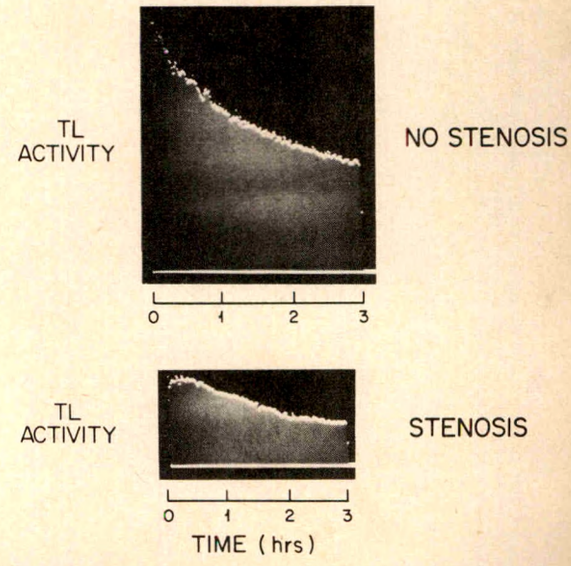

FIGURE 3. Representative probe-determined myocardial thallium (TL) clearance curves after norepinephrine for the no-stenosis and stenosis zones.

TABLE II Myocardial and Blood Thallium Washout Data

Dog	Fractional TI Washout		Time to Peak TI Activity (min)		Stress Blood Flow Ratio	Final TI Ratio	Blood TI Decay Constant			Myocardial Decay Constant λ

zone and 0.49 for the stenosis zone. Time to peak thallium activity was 1 minute for the no-stenosis zone and 7 minutes for the stenosis zone.

Table II lists the myocardial and blood thallium washout data for the 11 dogs. The mean fractional myocardial thallium clearance was significantly lower (0.47 ± 0.03) for the stenosis zone than the no-stenosis zone (0.57 ± 0.03) ($p < 0.0001$). The stress blood flow ratio (stenosis/no-stenosis zone = 0.27 ± 0.06) was significantly lower than the final thallium activity ratio (0.68 ± 0.07) ($p < 0.001$), consistent with thallium redistribution occurring between the time of thallium injection and 3 hours later.

Myocardial thallium activity in the stenosis zone peaked in a mean of 2.2 ± 0.6 minutes, then washed out biexponentially with an early mean decay constant of 0.0994 ± 0.0218 min^{-1} and a final decay constant of 0.0035 ± 0.0005 min^{-1}. Myocardial thallium activity in the no-stenosis zone peaked within 1 minute in all dogs, then washed out biexponentially with an early decay constant of 0.1003 ± 0.0232 min^{-1} and a final decay constant of 0.0043 ± 0.0003 min^{-1} ($p < 0.001$ vs stenosis zone). Blood thallium activity cleared triexponentially.

Discussion

Exercise thallium imaging is widely used to evaluate patients with chest pain. Thallium defects on initial postexercise images can represent either scar or ischemia. However, filling in of the defect, so-called thallium redistribution, is believed to differentiate ischemia from scar. For the most part, thallium images are interpreted qualitatively. Considerable training and experience is required to accurately interpret these images. Furthermore, there is considerable observer variance in the interpretations.[16] To overcome these shortcomings and in an attempt to improve the diagnostic accuracy, quantitative computer programs have been developed for interpreting serial patient thallium studies.[3–11] Normal limit profiles have been established for clearance based on studies in subjects with low probability for coronary disease. Berger et al,[11] using both distribution and clearance (absence of any washout) criteria, reported a sensitivity of 91% and specificity of 90%. Wackers et al[8] found that clearance was "almost uniform" in all myocardial segments. These investigators reported a sensitivity 89% and specificity of 95% for combined distribution and clearance criteria. Garcia and associates[9] detected coronary disease with clearance criteria alone in 2 of 20 patients. They found that 33 of 46 patients (72%) with "diffuse slow washout" of thallium had 3-vessel or left main coronary artery disease.[6] They also detected an additional 14% of diseased vascular distributions using clearance criteria.[7]

In the present study, exercise was simulated using a norepinephrine infusion. Mean heart rate, blood pressure and double product were all significantly increased by the norepinephrine infusion. However, differences do exist between this model and true exercise. With true exercise, blood flow and, thus, thallium delivery and uptake are increased in the large skeletal muscles. Therefore, although first-pass myocardial thallium uptake is the same, subsequent myocardial

uptake may be less with true exercise. Furthermore, true exercise usually produces a greater heart rate response and lesser blood pressure response compared with the norepinephrine model.

The present study demonstrates a reduced fractional thallium clearance rate from myocardium supplied by a stenosed coronary artery, when tracer was administered during exercise simulation using norepinephrine. Thus, these findings agree with clinical observations.[3–11] Whereas normally perfused myocardium showed a mean fractional clearance rate of 0.57 over 3 hours, all 11 dogs demonstrated reduced clearance rates distal to coronary stenoses. However, the normal value for fractional 3-hour clearance ranged from 0.32 to 0.68. Thus, the determinants of normal myocardial thallium clearance are probably multifactorial. Llaurado et al[17] stressed male rats by forced swimming for 2 hours, after which thallium was administered intravenously. They found a 27% clearance of thallium from normal myocardium between 30 and 180 minutes after administration. The differences between these results and the results of the present study may be in the lack of the first 30 minutes of clearance data in their study.

The mechanism of reduced thallium clearance from myocardium distal to a coronary stenosis after norepinephrine is unclear. However, neither transient nor persistent ischemia after normal myocardial thallium loading have an effect on clearance rates.[18,19] Thus, it is unlikely that persistent ischemia over the 3-hour redistribution period is the cause of reduced clearance from the stenosis-zone myocardium. Furthermore, because the effects of norepinephrine on the no-stenosis-zone myocardium are short-lived after the drug is discontinued, it is unlikely that persistent hyperemia in this zone is causing a relatively slowed clearance from the stenosis zone. Thus, the most likely cause for the slowed clearance from the stenosis zone is the difference in initial thallium uptake during the norepinephrine infusion. Compared with the normal zone, a lower initial thallium concentration in the stenosis zone would provide a smaller gradient between this zone and the blood, and this should reduce clearance.

The present study confirms that thallium redistribution (thallium heterogeneity resolution over time) occurs after exercise in viable myocardium distal to a coronary stenosis. The mechanism of thallium redistribution in the exercise stimulation model was faster clearance of tracer from normal thallium compared with the clearance from myocardium distal to a stenosis. The mechanism is similar to that observed after dipyridamole.[13] This mechanism is different from that observed in transient or persistent ischemia resting dog models. Here, thallium redistribution is a result of clearance of tracer from normal myocardium and slow accumulation in ischemic myocardium.[20–24] Using an occlusion model with release of the occlusion after thallium administration, the initial defect rapidly resolves.[22] However, even with persistent stenosis, significant thallium redistribution occurs over 4 hours.[20] Gerry et al[25] also observed a flow-independent component to thallium redistribution in dogs with circumflex coronary artery stenoses undergoing either 20 or 120 minutes of atrial pacing. Redistribution occurred despite the continued presence of pacing-induced reduced flow in the circumflex-perfused endocardial tissue. Llaurado et al[26] showed that the delayed myocardial uptake of thallium is not a result of reintroduction of tracer into the blood from other body organs.

Relation of Myocardial Salvage to Size of Myocardium at Risk in Dogs

ANDREW ZALEWSKI, MD, SHELDON GOLDBERG, MD, DUARTE B. FARIA, MD, RICHARD KROL, MD, and PETER R. MAROKO, MD

Infarct size varies in untreated animals subjected to coronary artery occlusion at the same anatomic site. The relation between the hypoperfused zone and the magnitude of myocardial salvage when different pharmacologic interventions are used remains to be established. Thus, in 95 anesthetized dogs, 1 minute after left anterior descending coronary occlusion, technetium-99m-labeled albumin microspheres (8 mCi) were injected into left atrium for the assessment of the hypoperfused zone. Fifteen minutes after coronary occlusion 42 dogs were randomized into a control group and 53 into a treated group. In the treated group, 6 dogs received nifedipine, 0.35 μg/kg followed by 2.4 μg/kg/hour; 7 received diltiazem, 0.2 mg/kg followed by 0.9 mg/kg/hour; 13 received bepridil, 2.5 mg/kg; 9 received cytochrome C, 2.5 mg/kg; 8 received rutosides, 200 mg/kg; and 10 received nifedipine plus cytochrome C. All drugs were administered intravenously. At 6 hours the dogs were killed and their hearts were cut into 3-mm-thick slices. Infarct size was determined by triphenyltetrazolium chloride staining; the hypoperfused zone was delineated by autoradiography. The dogs were retrospectively subgrouped as follows: those with small hypoperfused zones, i.e., less than 15% of the left ventricle (controls n = 8, treated n = 7) and those with large hypoperfused zones, i.e., more than 15% of the left ventricle (controls n = 34, treated n = 46). In dogs with large hypoperfused zones, treatment salvaged 42 ± 3% of the myocardium destined to undergo necrosis, whereas in those with small hypoperfused zones 78 ± 10% of myocardium was salvaged ($p < 0.001$). A close inverse correlation between the hypoperfused zone and infarct size reduction was found in all treated dogs. In conclusion, more striking salvage of ischemic myocardium was observed in dogs with a small area at risk when different interventions were used after coronary artery occlusion. Thus, the initial size of the hypoperfused zone is an important determinant of the effectiveness of various pharmacologic treatments in reducing infarct size.

(Am J Cardiol 1985;56:974–977)

Coronary artery occlusion at the same anatomic site results in significant variation in subsequent infarct size.[1] This variability is not related to changes in the major determinants of myocardial oxygen consumption, but rather, is dependent on the amount of myocardium supplied by an occluded artery, i.e., the area at risk.[1] Several investigators[1–4] have shown a close linear correlation between the size of the area at risk and subsequent necrosis in untreated animals. Therefore, the myocardium at risk is an important predictor of infarct size. Several pharmacologic interventions have been described[3,5–8] that reduce the area at risk that evolves to necrosis; thus, it is pertinent to assess whether the effectiveness of these interventions is modified by the initial area at risk. A preliminary study with methoxyverapamil[8] revealed that the drug is more effective in reducing infarct size in dogs with a small area at risk than in those with large area at risk. However, whether these findings with methoxy-verapamil are more universally applicable when other interventions are used to reduce infarct size is not known. The aim of this study was to assess the relation between the initial area at risk for infarction and the magnitude of reduction of infarct size using various pharmacologic interventions.

Methods

Animal preparation: Ninety-five dogs were anesthetized with sodium pentobarbital, 20 mg/kg intravenously, intubated endotracheally and ventilated with room air using a volume respirator (Harvard Apparatus). Systemic arterial pressure (Statham P23Db pressure transducer) and electrocardiographic lead aVF were recorded continuously throughout the 6-hour experiments on a polygraph (Gould Instruments). A thoracotomy was performed through the fifth intercostal space and the left anterior descending coronary artery was permanently occluded proximal to the first diagonal branch for 6 hours.

Experimental protocol: One minute after coronary occlusion, 2×10^6 (8 mCi) technetium-99m-labeled albumin microspheres, 20 μm in diameter, (3M Co.) were injected into

the left atrium for the subsequent determination of the hypoperfused zone i.e., area at risk for infarction. At 15 minutes after coronary occlusion, 42 dogs were randomized to a control group and 53 to a treated group. Dogs in the treated group received various drugs intravenously: 6 received nifedipine, 0.35 μg/kg as a loading dose followed by 2.4 μg/kg/hour; 7 received diltiazem, 0.2 mg/kg as a loading dose followed by 0.9 mg/kg/hour; 13 received bepridil, 2.5 mg/kg; 9 received cytochrome C, 2.5 mg/kg; 8 received rutosides, 200 mg/kg; and 10 received nifedipine in combination with cytochrome C. Six hours after occlusion, the dogs were killed with an intravenous injection of potassium chloride and their hearts were excised. The left ventricles were then frozen at −70°C and cut into 3-mm-thick slices from the apex to the site of occlusion. Retrospectively, all dogs were arbitrarily separated into groups according to the initial area at risk: those with hypoperfused zones less than 15% of the left ventricle (controls n = 8, treated n = 7); and those with hypoperfused zones more than 15% of the left ventricle (controls n = 34, treated n = 46). All interventions were represented in both groups i.e., with large and small hypoperfused zone, respectively.

Infarct size measurements: To assess the extent of myocardial infarction, the slices were incubated in a 1.5% solution of triphenyltetrazolium chloride (Sigma Chemicals) for 10 minutes at 37°C. The reaction was stopped by rinsing with a 10% solution of formaldehyde, which enhances the red color of the normal myocardium contrasting with the pale yellow of the damaged tissue.[9] The normal and necrotic areas were then planimetered (Apple II computer). The extent of the hypoperfused zone was determined on the same slices. The slices were placed on radiographic films (Cronex 4 E.I. DuPont) and autoradiographed for 13 hours. To clearly identify their borders, soft radiographs (i.e., 25 KvP 100MAS) were also obtained and superimposed on the autoradiographs. The contours of the slices and the "cold spots"—areas of hypoperfusion—were delineated on transparent plastic sheets and planimetered (Apple II computer).

In each dog the following variables were calculated: (1) Percent of left ventricle that showed myocardial necrosis. This zone defined the infarct size. (2) Percent of left ventricle that was initially hypoperfused as determined by autoradiography ("cold spot"), and defined the hypoperfused zone. (3) Percent of the hypoperfused zone that evolved to infarction. This was calculated by dividing infarct size by the hypoperfused zone and multiplying by 100, and was used to examine whether the intervention was effective in reducing myocardial damage. (4) Effectiveness of the interventions was assessed by calculating reduction in the infarct size/hypoperfused zone ratio compared with the control group. Furthermore, percent reduction in infarct size was examined as a continuous function of the hypoperfused zone.

Statistical analysis: The results were expressed as mean ± standard error of the mean. A Student unpaired *t* test was used for comparisons between the control and treated groups. A p value <0.05 was considered significant.

Results

To verify whether the control and treated groups were comparable before intervention, heart rate and mean arterial pressure were analyzed. Accordingly, 15 minutes after coronary artery occlusion, i.e., after randomization but before the interventions were begun, heart rate was 133 ± 5 and 118 ± 3 beats/min in the control and treated groups, respectively (difference not significant [NS]). Mean arterial pressure at 15 minutes after coronary occlusion was 102 ± 4 and 99 ± 4 mm Hg (NS) in the control and treated groups, respectively.

Analysis of the extent of myocardial damage: The hypoperfused zone was 23 ± 1% of the left ventricle in the control group (n = 42) and 25 ± 1% in the treated group (n = 53) (NS). Infarct size was 21 ± 1% of the left ventricle in the control group and 14 ± 2% in the treated group (p <0.005). In the control group, an average of 92 ± 1% of the hypoperfused zone evolved to infarction, whereas in the treated group 50 ± 3% evolved to infarction, (p <0.001), indicating significant salvage of ischemic myocardium (Fig. 1).

Relation between size of the hypoperfused zone and myocardial salvage: When dogs were separated into groups according to initial risk area, 20 ± 9% of the hypoperfused zone evolved to infarction in dogs receiving treatment when the hypoperfused zone was less than 15% of the left ventricle (p <0.001 vs respective controls) and 54 ± 3% in dogs when the hypoperfused zone was more than 15% of the left ventricle (p <0.001 vs respective controls) (Fig. 2). The infarct size/hypoperfused zone ratio was 90 ± 1% and 93 ± 2% in controls with the hypoperfused zone less than 15% of the left

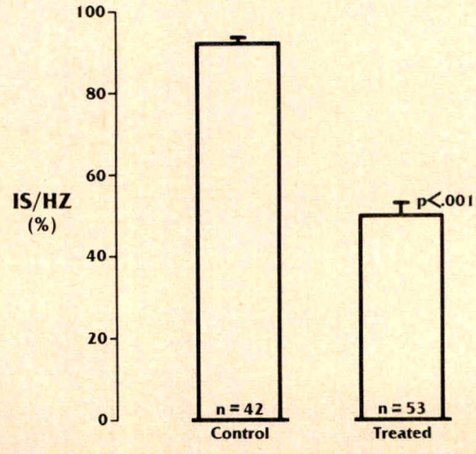

FIGURE 1. Percent of the hypoperfused zone (HZ) that evolved to necrosis, i.e., ratio of infarct size (IS) to HZ, in the control and treated groups, regardless of the initial size of the HZ. Values are mean ± standard error of the mean.

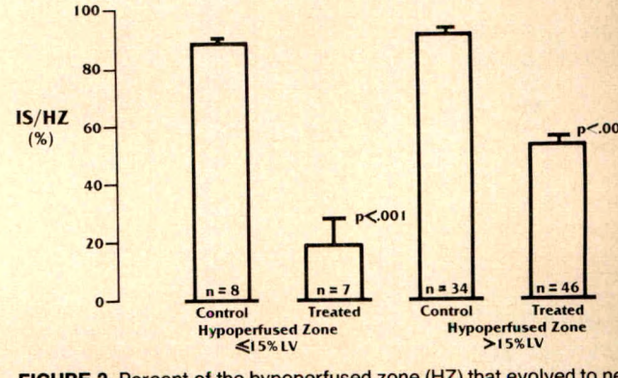

FIGURE 2. Percent of the hypoperfused zone (HZ) that evolved to necrosis, i.e., ratio of infarct size (IS) to HZ, with respect to the initial size of the HZ. Values are mean ± standard error of the mean. LV = left ventricle.

ventricle and the hypoperfused zone more than 15% of the left ventricle, respectively (NS) (Fig. 2).

Myocardial salvage as measured by reduction of the infarct size/hypoperfused zone ratio in the 2 treated groups is shown in Figure 3. In dogs with a hypoperfused zone more than 15% of the left ventricle treatment salvaged 42 ± 3% of the myocardium destined to undergo necrosis, whereas in those with the hypoperfused zone less than 15% of the left ventricle significantly more myocardium was salvaged: 78 ± 10% ($p < 0.001$). When infarct size reduction in the treated groups was analyzed as a function of the risk area (Fig. 4), a close inverse correlation was found [infarct size reduction (percent) = 127.52 − 3.51 (hypoperfused zone); n = 53, r = −0.74].

Hemodynamics: Heart rate measured at 15 minutes, 3 hours and 6 hours after coronary occlusion was 124 ± 16, 94 ± 5 and 119 ± 16 beats/min in the treated group with the hypoperfused zone less than 15% of the left ventricle and 117 ± 3, 108 ± 3 and 112 ± 4 beats/min in the treated group with a hypoperfused zone greater than 15% of the left ventricle (NS). Mean arterial pressure at 15 minutes, 3 hours and 6 hours after coronary occlusion was 102 ± 9, 107 ± 13 and 102 ± 12 in the treated group with a hypoperfused zone less than 15% of the left ventricle and 99 ± 3, 111 ± 4 and 107 ± 3 mm Hg in the treated group with a hypoperfused zone more than 15% of the left ventricle (NS).

Discussion

This study indicates that the effectiveness of pharmacologic intervention in reducing infarct size is related to the size of the initial risk area, i.e., hypoperfused zone. Thus, more striking salvage of ischemic myocardium was observed when the hypoperfused zone was small.

Pathophysiology of the area at risk: The size of a myocardial infarction depends on the magnitude of collateral flow at the border of the hypoperfused zone as well as on myocardial oxygen consumption.

Several investigators[4,10,11] reported the presence of a flow gradient from the border zone to the center of an infarct, with a modest increase of collateral flow to the epicardial portion of the ischemic zone 24 hours after the onset of ischemia.[10–12] Because our study was limited to 6 hours of coronary occlusion, spontaneous changes in collateral flow within the ischemic zone were unlikely to occur. Striking myocardial salvage in dogs with smaller risk areas may be attributed only in part to the increase in collateral flow within the ischemic zone caused by some of the interventions used in this study, such as nifedipine[13,14] or diltiazem.[15] In contrast, other treatments, such as rutosides[6] or cytochrome C (Maroko PR, Krol R: unpublished data), did not change regional myocardial blood flow after coronary occlusion.

These findings indicate that marked myocardial salvage in dogs with a small area at risk does not require an absolute increase in collateral perfusion. The observed difference in infarct size reduction was also not related to changes in myocardial oxygen consumption, as indicated by similar heart rates and arterial pressures between the treated groups with small and large risk areas.

Determination of area at risk: Several investigators[1,4,16,17] defined the area at risk by postmortem injection of radiopaque gels or a dye solution into the occluded and nonoccluded coronary arteries. These methods, however, were limited by penetration of the dye from the normal zone into the infarcted region[4] and the need for artificial pressure required for filling of coronary arteries with a given material.[1,4,17] More im-

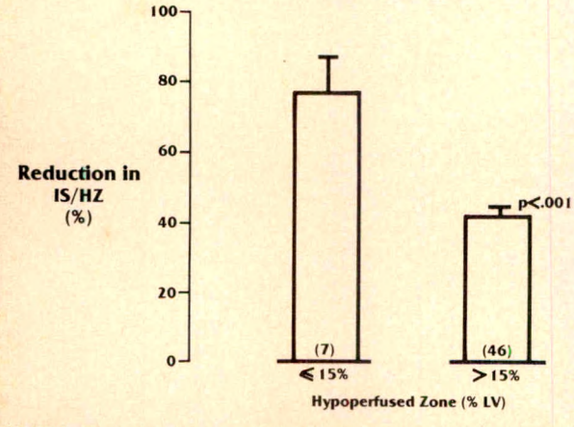

FIGURE 3. Reduction in infarct size/hypoperfused zone ratio (IS/HZ) in 2 treated groups according to the initial size of the hypoperfused zone. More striking myocardial salvage was observed in the treated group with the hypoperfused zone of less than 15% of the left ventricle (LV). Values are mean ± standard error of the mean.

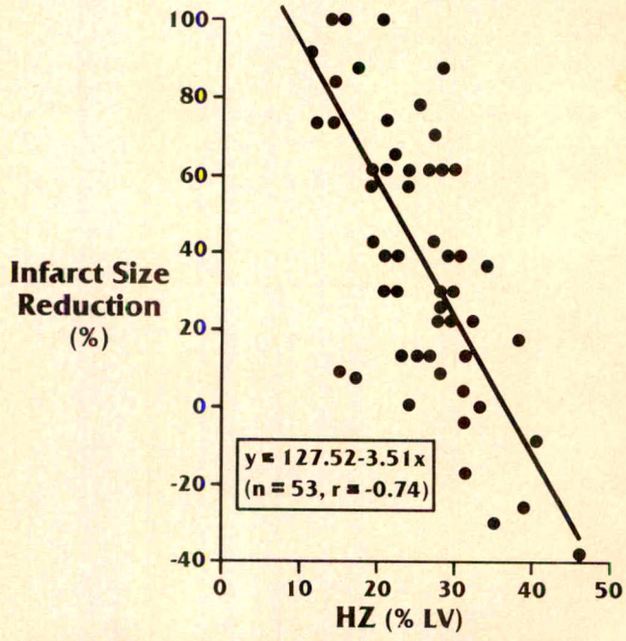

FIGURE 4. Relation between hypoperfused zone (HZ) expressed as a percent of the left ventricle (% LV) and infarct size reduction, i.e., myocardial salvage in the treated group. A close inverse correlation was found (r = −0.74), indicating that myocardial salvage is a continuous function of the initial risk area.

portant, postmortem techniques may not accurately delineate the hypoperfused areas present in vivo at the moment of coronary occlusion.

The area at risk can also be determined in vivo by contrast echocardiography[18] or injection of dye[14] or radioactive material into the left atrium[3,19] after coronary occlusion. The last technique, using postmortem autoradiography, allows for precise measurement of the hypoperfused zone present at the time of injection of the radioactive material. In our study, injection of technetium-99m-labeled albumin microspheres into the left atrium was performed after coronary occlusion before any intervention was started. Thus, this experimental technique allowed not only for in vivo determination of the hypoperfused zone, but also the potential effect of pharmacologic interventions on the measured area of hypoperfusion was avoided.[17]

Limitations of the study: The present study has several limitations. All dogs underwent occlusion of the proximal left anterior descending coronary artery; therefore, a smaller number of dogs had hypoperfused zones of less than 15% of the left ventricle. However, this emphasizes the importance of the risk area determination even with proximal coronary artery occlusions, as collateral-dependent hypoperfused zone may vary substantially. Furthermore, the investigation of interventions aimed at reducing infarct size are best studied when the initial risk area is accurately determined. The comparison of the treated groups with hypoperfused zones less than and greater than 15% of the left ventricle is arbitrary, but further analysis showed that infarct size reduction is a continuous function of the initial hypoperfused zone (Fig. 4). Therefore, the effectiveness of the treatment was inversely related to the initial areas at risk.

Clinical implications: Few data exist concerning the relation between risk area and infarct size in patients. Lee et al[20] showed a close linear correlation between the size of the vascular bed at risk and the infarcted zone in an autopsy study limited to fatal infarcts. In patients with multivessel coronary artery disease and collateral circulation supplied by a jeopardized coronary artery, acute coronary artery occlusion may lead to ischemia in the collateral-dependent zone. This phenomenon could be responsible for "ischemia at distance"[21] and is associated with a high risk of mortality.[22] This underscores the prognostic importance of the concept of area at risk. Although interpolation of our experimental findings to patients with acute myocardial infarction is difficult, preliminary data suggest that patients with a small risk area may benefit more from pharmacologic interventions aimed at salvaging ischemic myocardium. Gold et al[23] showed that intravenous propranolol administration resulted in striking reduction of ST-segment elevation in patients with acute myocardial infarction only if residual flow to the infarcted zone was preserved, i.e., the risk area was relatively small.

In conclusion, the size of the hypoperfused zone i.e., risk area, is an important determinant of the magnitude of myocardial salvage when different pharmacologic interventions are used in the setting of coronary artery occlusion in dogs. We postulate that the striking infarct size reduction in dogs with a small hypoperfused zone was related to the presence of collateral circulation, which afforded better penetration of the agents into the ischemic zone.

Usefulness of Defibrotide in Protecting Ischemic Myocardium from Early Reperfusion Damage

CHRISTOPH THIEMERMANN, BSc, PETRA LÖBEL, BSc, and KARSTEN SCHRÖR, MD

Defibrotide, a partially depolymerized polydeoxyribonucleotide obtained from mammalian lungs, was found to stimulate prostacyclin (PGI_2) production and to possess significant antithrombotic and fibrinolytic activities. The present study was designed to evaluate the actions of defibrotide on feline myocardial ischemia, produced by 3 hours of occlusion of the left anterior descending coronary artery (LAD) and followed by 2 hours of reperfusion. Intravenous administration of defibrotide (32 mg/kg/hour subsequent to a 32 mg/kg bolus injection), beginning 30 minutes after LAD occlusion, resulted in a 60% reduction in loss of CK specific activity from ischemic myocardium at 5 hours, while the nonischemic myocardium remained unaffected. Defibrotide largely antagonized the increase in ST segment during LAD occlusion and prevented the appearance of a Q wave during early reperfusion, which was found in all vehicle-treated cats. Although 2 of 8 vehicle-treated cats died from ventricular fibrillation and another had severe ventricular tachyarrhythmia, none of the defibrotide-treated cats had similar severe changes in the electrocardiogram and all 7 cats survived the 5-hour observation period. Defibrotide had no direct action on general hemodynamic functions. In a separate set of experiments, defibrotide (0.1 mg/ml) produced an 8- to 10-fold stimulation of PGI_2 release. The data suggest a remarkable protective potential of defibrotide on reperfusion damage of the ischemic myocardium, which may be associated with a PGI_2-related mechanism.

(Am J Cardiol 1985;56:978–982)

Myocardial damage often results from acute thrombotic occlusion of a large coronary artery. Thus, surgical reopening of the occluded vessel and pharmacologic thrombolysis with streptokinase or urokinase[1] are the most direct approaches to supply the jeopardized myocardium with oxygen and other nutrients, necessary for cell survival. However, there is always an interval after the acute event before attempts to reopen the occluded vessel can be started. During this period a significant degree of tissue injury may have already developed.[2] This will eventually lead to the "reperfusion damage"[3] caused by cellular Ca^{++} overload[4] and increased free radical formation[5] after restitution of blood supply. Thus, successful thrombolysis may initially further aggravate myocardial tissue injury.[6]

Noxious stimuli to the cell surface also increase the local fatty acid release. Fatty acid peroxides can specifically inhibit prostacyclin (PGI_2) generation (i.e., formation of a tissue-protective factor) at a time when formation of other eicosanoids including thromboxanes are probably increased. PGI_2[7] and a PGI_2 mimetic[8] were found to protect the ventricular myocardium of the cat from both ischemic injury and reperfusion damage.[9] An alternative approach is to stimulate the endogenous PGI_2 production. Defibrotide is a polydeoxyribonucleotide obtained by controlled depolymerization of DNA from mammalian lungs. The molecular weight of single strands is about 20,000 daltons.* Defibrotide has significant antithrombotic-,[10] profibrinolytic-[11] and plasminogen-activating properties.[12] This profile of actions made the compound interesting as a new therapeutic approach to improve preservation of ischemic myocardium.

This study was designed to evaluate the actions of defibrotide on functional and biochemical variables of myocardial tissue damage in an in vivo model of ischemia plus reperfusion. Additionally, the influence of defibrotide on cardiac PGI_2 and thromboxane formation was investigated in the isolated guinea pig heart.

Methods

Surgical techniques: Adult cats of either sex (body weight 2.5 to 4.0 kg) were anesthetized with 30 mg/kg of pentobarbital sodium intravenously. All cats underwent tracheotomy, and positive pressure ventilation was instituted by means of a small animal respirator (Schuler). After thoracotomy, the left anterior descending artery (LAD) was prepared and occluded at time 0. This occlusion was maintained for 3 hours and then followed by 2 hours of reperfusion, initiated by removal of the ligature. All cats were killed at 5 hours.

Physiologic measurements: A catheter was placed in the right femoral vein for infusion of the substances; another was

placed in the right atrium through the right jugular vein for blood sampling. A third catheter, placed in the left femoral artery, was connected with a Statham P23Db pressure transducer to determine mean arterial blood pressure. Heart rate was determined from the systolic pressure curves by a Hellige Recomed measuring unit (Hellige). Changes in the electrical activity of the myocardium were detected by a standard lead electrocardiogram (ECG).[8]

Platelet aggregation studies: The platelet count was determined in right atrial blood by using interference phase contrast microscopy (see Ref. 8 for details).

Platelet ATP secretion: Platelet ATP secretion was measured in whole blood using a Lumi-aggregometer (Chronolog). One milliliter of right atrial blood was taken in citrate (1:10/v:v) and 1 minute later stimulated ex vivo at 37°C by the addition of 2 μg/ml of collagen (Hormon-Chemie). The samples were stirred at 1,200 rpm. ATP secretion was measured by the luminescence technique following recommendations of the producer. Synthetic ATP (Sigma) was used as the standard.

Myocardial biochemical measurements: At the end of the 5-hour experimental period, the hearts were excised and immediately placed into cold physiologic saline solution. The left ventricular wall of the heart was divided into normal and ischemic myocardium by visual inspection of the myocardial surface. Samples that weighed about 400 mg from the center of the ischemic region and of the nonischemic left ventricular tissue were excised. These tissue samples were homogenized and used for determination of CK-specific activity as previously described.[7,13] The assay kit was purchased from Boehringer.

Evaluation: LAD occlusion was performed at time 0. At 30 minutes, an intravenous bolus injection of 32 mg/kg of defibrotide (Crinos Pharmaceuticals) was performed. The substance was continuously infused in a dose of 32 mg/kg/hour for the remainder of the experiment. Cats that did not receive defibrotide were treated with physiologic saline solution (vehicle) at the same infusion rate (0.9 ml/hour). At 3 hours, the LAD occlusion was removed to allow a subsequent 2-hour reperfusion period until the end of the experiment at 5 hours. Blood samples for platelet studies were taken at 0, ½, 1, 3 and 5 hours. At the same time, platelet ATP secretion was determined ex vivo. Mean arterial blood pressure, heart rate and ECG were continuously recorded. Detailed analysis, however, was only performed at the times mentioned.

Four groups of cats were studied: cats with occluded LAD treated with vehicle (n = 9) or defibrotide (n = 7), and sham-operated cats subjected to all of the same operative procedures except closure of the LAD and treated with vehicle (n = 5) or defibrotide (n = 2). Because the 2 sham-operated, defibrotide-treated cats did not differ from the vehicle-treated controls, these data were pooled.

Prostacyclin formation by the heart: The action of defibrotide on PGI_2 biosynthesis was investigated in a separate set of experiments, using a platelet-perfused in vitro heart model.[14] Briefly, washed human platelets (4×10^8/min) were continuously infused through a Langendorff-perfused guinea pig heart. The release of PGI_2 into the coronary effluent was measured by radioimmunoassay in terms of the chemically stable degradation product 6-keto-$PGF_{1\alpha}$. The cross-reactivity of the antibody amounted to less than 0.1% with the agents used in this study: $PGF_{1\alpha}$, 15-keto-$PGF_{1\alpha}$, 15-keto-13,14-dihydro-$PGF_{1\alpha}$; 0.2% with PGD_2, 0.4% with PGE_3, 2.5% with 6,15-diketo-$PGF_{1\alpha}$ and 3% with 6,15-diketo-13,14-dihydro $PGF_{1\alpha}$. Measurements were performed before and in 10-minute intervals during platelet administration. Defibrotide (0.1 mg/ml) and urokinase (Ukidan®) (10 IU/ml) were continuously infused for 90 minutes. In some experiments indomethacin (3 μg/ml) (Merck, Sharp & Dohme) was used to block cyclooxygenase activity.

Statistical analysis: The mean ± standard error of the mean of the number of observations are used in the text. Statistical comparisons were made with the Student 2-tailed t test. A p value ≤ 0.05 was considered significant.

Results

Defibrotide effects on general hemodynamics: Initially, the mean arterial blood pressure was not different in the several groups of cats studied; it ranged from 120 to 140 mm Hg. In the cats subjected to LAD occlusion plus reperfusion and treated with vehicle, the arterial blood pressure decreased from 140 ± 4 mm Hg at time 0 to 133 ± 4 mm Hg at 5 hours. Cats treated with defibrotide had an initial blood pressure of 135 ± 5 mm Hg and 115 ± 6 mm Hg at 5 hours. These values at 5 hours were not different from each other ($p > 0.05$).

The average heart rate initially ranged from 170 to 195 beats/min in the cats subjected to LAD occlusion and was reduced by about 15% of this control level in the course of the experiment. These differences between vehicle- and defibrotide-treated cats were not significant ($p > 0.05$).

Defibrotide effects on platelet aggregate formation: Initially, the free platelet number in right atrial blood ranged from 400,000 to 550,000 platelets/μl (100%) and was uniformly decreased by 20 to 25% in all groups of cats during the operative procedures. After LAD occlusion, there was a further 20% decrease in free platelet count, which then remained unchanged in vehicle-treated cats. Even after institution of reperfusion at 3 hours, there was no restitution of the original platelet number, i.e., no resolution of platelet aggregates. There was no change in sham-operated cats nor

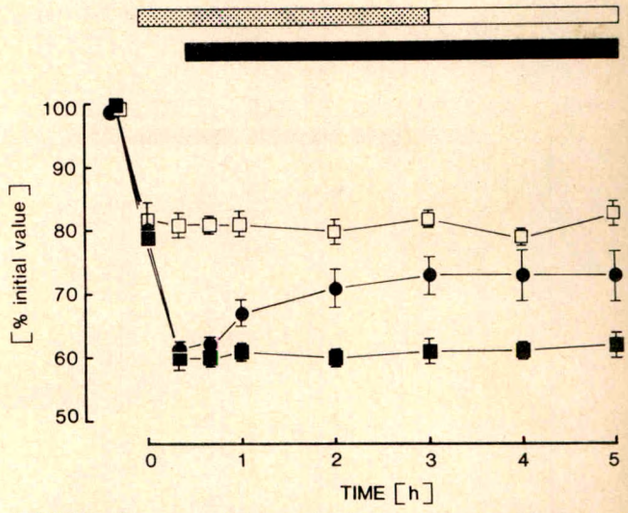

FIGURE 1. Changes in the free platelet count in cats subjected to 3 hours of occlusion of the left anterior descending coronary artery (LAD) (**stippled bar**) followed by 2 hours of reperfusion (**open bar**). The cats were treated with vehicle (**squares**) or defibrotide (32 mg/kg/hour) (**circles**) and subjected to LAD occlusion (**filled symbols**) or sham operation (**open symbols**). Each point represents the mean ± standard error of the mean of 7 to 8 experiments. In comparison with cats with occluded LAD treated with vehicle, there was a significant elevation of the free platelet count in defibrotide-treated cats at 2 to 5 hours (h).

TABLE I ATP Secretion in Whole Blood Ex Vivo of Cats Subjected to Left Anterior Descending Coronary Artery Occlusion (LAD) + Reperfusion and Treated with Vehicle or Defibrotide

Group	No.	ATP Release (% of Control = Time 0)				
Time after LAD occlusion (hour)		0	30 minutes	1½	3	5
Vehicle	7	100%	88 ± 15	67 ± 7	75 ± 24	80 ± 23
Defibrotide	6	100%	86 ± 14	36 ± 10	29 ± 6	23 ± 5

Values are mean ± standard error of the number of observations. Compared with the group treated with vehicle, the ATP secretion in the defibrotide-treated group was significantly reduced at 1.5, 3 and 5 hours ($p < 0.05$).

any direct action of defibrotide on platelet number in these cats (not given). However, cats with LAD ligation treated with defibrotide had a significant increase in the free circulating platelet count ($p < 0.05$ at 2 to 5 hours compared with values after vehicle treatment) (Fig. 1).

Defibrotide effects on platelet ATP secretion: Cats with occluded LAD treated with vehicle showed slightly reduced ATP secretion during the course of the experiment ($p > 0.05$). This ATP release was highly variable and not different from that of sham-operated controls at any time of the experiment. However, cats subjected to LAD occlusion and treated with defibrotide had a considerable reduction in ATP release which was significant at 1.5, 3 and 5 hours (Table I).

Defibrotide effects on ST-segment elevation: LAD occlusion was associated with rapidly developing ST-segment elevation, which was greatest at 3 hours (Fig. 2). Removal of the occlusion at this time resulted in a rapid decrease, although a significant ST-segment elevation greater than that in sham-operated controls was still observed ($p < 0.05$ from 20 minutes to 5 hours). The cats with LAD occlusion treated with defibrotide had a significant increase in ST segment at 20 minutes, i.e., before starting drug administration. After starting infusion, there was no further increase in the ST segment; in fact, there was a reduction, almost similar to the values in sham-operated, vehicle-treated cats. The differences between the cats with LAD occlusion treated with vehicle and the defibrotide group were significant at 1 to 3 hours ($p < 0.05$). At 4 and 5 hours, during reperfusion, there was no significant difference between cats with LAD occlusion that received defibrotide and sham-operated controls.

Defibrotide effects on R-wave loss: Within a few minutes of reperfusion, there was a decrease in R-wave amplitude and appearance of a Q wave, suggestive of ventricular necrosis. Two of 8 vehicle-treated cats died from ventricular fibrillation within 20 minutes of reperfusion; another had ventricular tachycardia and frequent ventricular extrasystoles that did not lead to lethal fibrillation. No such changes were observed in defibrotide-treated cats.

Defibrotide effects on myocardial CK activity: Ischemic myocardium subjected to reperfusion exhibited more than 80% loss of CK specific activity. No such changes were observed in the nonischemic area of the left ventricle of the same hearts. As summarized in Figure 3, the CK-specific activity in the ischemic area of defibrotide-treated cats ($p < 0.01$) was as much as 3-fold higher than in vehicle-treated cats, although still significantly lower than in the nonischemic area of the

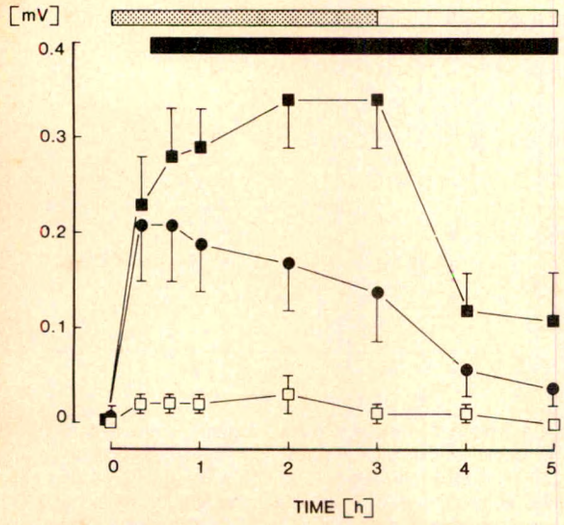

FIGURE 2. ST-segment elevation in cats subjected to 3 hours of occlusion of the left anterior descending coronary artery (LAD) followed by 2 hours of reperfusion. In comparison with cats with occluded LAD treated with vehicle (**filled squares**), there was a significant reduction of ST-segment elevation in defibrotide-treated cats with LAD occlusion (**filled circles**) at 1 to 5 hours (h).

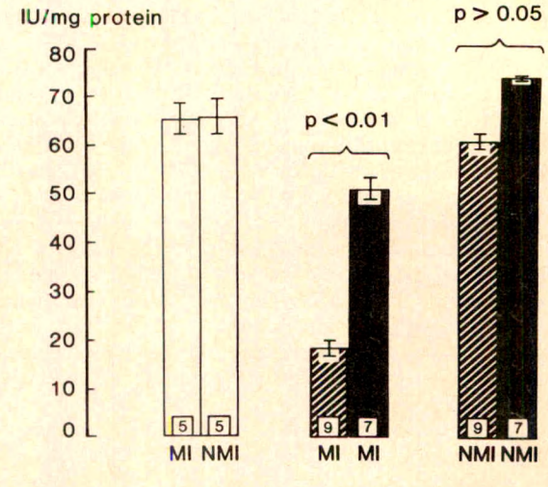

FIGURE 3. Creatine kinase specific activity in ischemic (MI) and nonischemic (NMI) areas of left ventricular myocardium of cats subjected to 3 hours of occlusion of the left anterior descending artery followed by 2 hours of reperfusion. The cats were treated with vehicle (**hatched columns**) or defibrotide (**black columns**). **Open columns** depict sham-operated, vehicle-treated controls. Numbers indicate the number of cats studied.

same hearts ($p < 0.05$). This result might not be explained by any specific action of defibrotide on the enzyme itself as seen in 2 additional, sham-operated cats treated with the agent. The CK-specific activity was 78 and 80 IU/mg of protein, respectively, and not different from the vehicle-treated, sham-operated controls.

Defibrotide effects on prostacyclin biosynthesis: Infusion of platelets through an isolated heart was not associated with any changes in basal PGI_2 release. However, if defibrotide was added to the system, the PGI_2 release was considerably enhanced. This effect was blocked by indomethacin pretreatment and was not seen when urokinase instead of defibrotide was used (Fig. 4). Details of the complex platelet studies require particular comments and will be reported separately. For the present study, the capacity of the agent to stimulate cardiovascular PGI_2 release should be demonstrated. Two additional findings are particularly noteworthy: defibrotide did not stimulate PGI_2 in absence of platelets and also did not specifically alter thromboxane release. Thus, defibrotide appears to be a selective stimulator for PGI_2.

Discussion

Myocardial protection by defibrotide: Earlier studies in the ischemia + reperfusion model of the cat have shown that CK loss from the ischemic area of left ventricular myocardium is 2- to 3-fold greater after 3 hours of LAD occlusion + 2 hours of reperfusion than after 5 hours of permanent LAD ligation.[9] This enzyme loss was found to be inversely proportional to the extent and severity of myocardial cell damage.[15] Defibrotide inhibited the CK loss from ischemic myocardium. This is highly suggestive of improved preservation of tissue integrity by the compound. This finding is corroborated by the inhibition of Q-wave development in the ECG, a widely accepted sign for irreversible cell injury as well as the prevention of fatal arrhythmias.

Recent investigations by Niada et al[16] demonstrated protective actions of defibrotide on ischemic cat myocardium subjected to 5 hours of permanent LAD occlusion. In these experiments, administration of defibrotide was begun 3½ hours before LAD occlusion; in our experiments, infusion was begun at only 30 minutes after LAD occlusion, i.e., at a time when significant alterations in myocardial function were already detectable, such as a considerable increase in the ST segment. Thus, our findings not only demonstrate the efficacy of defibrotide in preventing reperfusion damage but also show that the compound may be valuable for a real therapeutic approach (i.e., successful use after a period of ischemia had occurred).

Defibrotide actions on hemostasis: Reperfusion allows exaggerated platelet entry (10- to 30-fold) into the jeopardized region of left ventricular myocardium.[17,18] This may explain the sustained depression of free platelet count during reperfusion. Defibrotide did redissolve preformed platelet aggregates in vivo and inhibited platelet ATP secretion, although the compound does not possess antiplatelet properties in vitro. Stimulation of vascular PGI_2 by defibrotide could explain these apparent discrepancies, because similar antiplatelet effects have been found in this model with administration of PGI_2 mimetics.[9] Certainly, defibrotide may additionally improve the blood supply to the border zone of the developing infarct by its fibrinolytic activity.[10–12]

Prostacyclin stimulation with defibrotide: Myocardial ischemia is associated with a large increase in tissue free fatty acids[21] and enhanced formation of thromboxane A_2.[20] Reperfusion will increase free fatty acid washout and may initiate the formation of free radicals as toxic by products of an abnormal oxidative metabolism.[5] Lipid peroxidation products will inhibit PGI_2 biosynthesis. Thus, reduced formation of PGI_2 could contribute to the reperfusion injury of ischemic myocardium, whereas supply with PGI_2 will afford protection.[21] However, drug-induced stimulation of PGI_2 in vivo is difficult to assess because of its instability and rapid enzymatic metabolism.[22] Also, the use of cyclooxygenase-blocking agents to demask any enhanced PGI_2 formation in vivo may be inappropriate because of known but unidentified reasons for their failure[23] or effectiveness[24] in beneficially influencing the tissue damage in myocardial ischemia in the cat. We therefore, have decided to measure the influence of defibrotide on PGI_2 formation in a separate experimental design that allows determination of this compound in terms of a stable degradation product in the absence of significant enzymatic transformations.[14] These studies have shown long-lasting PGI_2 stimulation by defibrotide in the presence of platelets exceeding the basal PGI_2 release 8- to 10-fold. We were not able to demonstrate a similar effect with urokinase at an equieffective fibrinolytic concentration. Thus, although fibrinolytic- and plasminogen-activating actions of defibrotide are similar to that seen after streptokinase or urokinase,[16] the former additionally stimulates coronary vascular PGI_2, whereas urokinase does not.

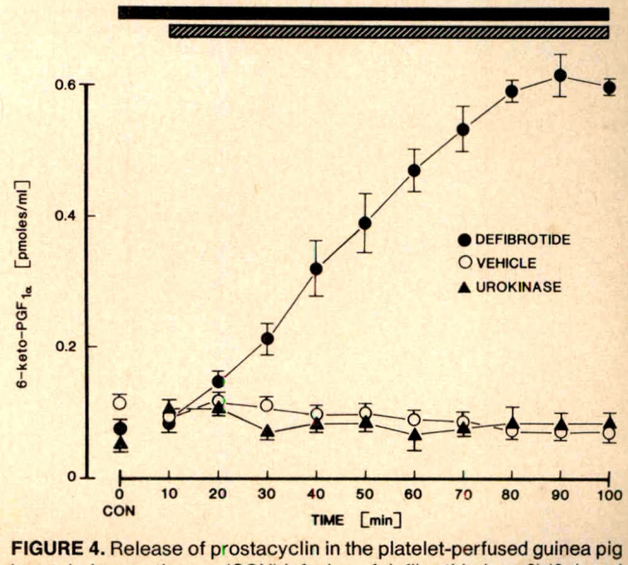

FIGURE 4. Release of prostacyclin in the platelet-perfused guinea pig heart during continuous (CON) infusion of defibrotide (n = 6) (0.1 mg/ml) but not by vehicle (n = 8) treatment. Urokinase (10 IU/ml) (n = 3) failed to stimulate prostacyclin.

In conclusion, defibrotide exerts an impressive protection of ischemic myocardial injury after reperfusion. All of the responses are close to those obtained with PGI_2 in similar experimental set-ups and may have this endogenous product as a common denominator. In agreement with this, a selective stimulation of coronary vascular PGI_2 by defibrotide has been demonstrated.

Innovative Products From Original Research

A number of important new therapeutic agents from Miles Pharmaceuticals are on the horizon. Promising research is underway in the fields of metabolic, infectious, cardiovascular and cerebrovascular disease.

These intense research and development programs reflect the vast increase in resources at Miles Pharmaceuticals in the past seven years, made possible by an association with one of the world's largest pharmaceutical companies.

Together, Miles Pharmaceuticals and its parent company have more than 200 years of ethical drug and medical experience. And, together, they are committed to on-going research that will improve the health of your patients. You'll be hearing more from Miles Pharmaceuticals in the months and years ahead.

The Healing Process in Normal Canine Arteries and in Atherosclerotic Monkey Arteries After Transluminal Laser Irradiation

GEORGE S. ABELA, MD, FILIPPO CREA, MD, JAMES M. SEEGER, MD, DAISY FRANZINI, MD, ALBERT FENECH, MD, SIGURD J. NORMANN, MD, ROBERT L. FELDMAN, MD, CARL J. PEPINE, MD, and C. RICHARD CONTI, MD

To evaluate the healing response of both normal and atherosclerotic arteries to laser radiation, 7 mongrel dogs and 4 hypercholesterolemic atherosclerotic monkeys underwent catheterization with a right Judkins catheter-optical fiber system designed to maximize arterial wall injury. Argon laser radiation was then delivered to the abdominal aorta and iliofemoral arteries. In the 11 animals, a total of 917 sites were irradiated in 33 arteries. Angiography did not reveal dissection or aneurysm formation; occlusive thrombosis was found in 2 arteries. Perforation of the arterial wall was a frequent complication. In animals killed between 1 hour and 4 days, light and electron microscopy of lased sites showed craters filled with a coagulum of blood and cellular debris with only a few adherent platelets. Healing occurred with a minimal inflammatory response and involved both fibroblasts and smooth muscle cells. Reendothelialization was seen in all animals killed between 7 and 14 days after lasing and was complete by 30 to 60 days. Within this period, no accelerated atherosclerosis was seen at lased sites in the hypercholesterolemic monkeys. It is concluded that transluminal lasing of normal arteries in dogs and in atherosclerotic arteries of monkeys is followed by healing and reendothelialization within a few weeks.

(Am J Cardiol 1985;56:983–988)

Lasers can recanalize occluded arteries.[1–5] During laser recanalization, however, areas of both normal and atherosclerotic arterial wall adjacent to the occluded segment may be inadvertently exposed to radiation. Therefore, before clinical application of this technique for recanalization, the irradiated arterial wall must heal without occlusive thrombus or aneurysm formation.[6] Also, one must know whether lasing in the presence of hypercholesterolemia accelerates atherosclerosis, similar to the response to other types of vascular trauma.[7–11]

This study was designed to investigate the immediate and short-term healing responses after laser irradiation of the arterial wall in normal and hypercholesterolemic atherosclerotic animals. With this technique, maximal laser trauma to the arterial wall is expected to occur. This type of trauma may occur during the course of laser recanalization. Energies known to vaporize atherosclerotic plaques were delivered through the optical fiber using a transluminal approach.[1,5] The transluminal approach was used to avoid an arteriotomy at the lased site, which itself could influence the results.[12,13]

Methods

Delivery of laser radiation: A continuous-wave argon laser (model 552, Laser Ionics) or Endocoagulator ML8, with energy peaks at wavelengths of 488 and 514 nm was used. Radiation was delivered through a 150-cm-long, 300-μm core silica optical fiber polished smooth at both ends. One end was aligned with the focused beam as it exited the laser, while the free end was used for lasing. Because of power attenuation along the fiber, radiation power was measured at the fiber tip with an external power meter. Because the fiber is not radiopaque, a metal marker was fixed at the tip allowing fluoroscopic visualization.

Protocol: *Mongrel dogs:* Eight mongrel dogs (19 to 22 kg) were anesthetized with an equal mixture of pentobarbital and fentanyl, intubated and allowed to ventilate spontaneously on a mixture of room air and halothane. A single dose of

* Thrombosis occurred in the segment perforated during fiber manipulation.
Ao = Aorta; LIF = left iliofemoral artery; N = normal; P = arterial perforation; PH = perivascular hematoma; RIF = right iliofemoral artery; T = thrombosis.

heparin (1,000 IU) was administered intravenously before catheterization. No antiplatelet agents were used. A No. 8Fr right Judkins catheter (Cordis Corp.) was introduced through a right carotid cutdown and advanced to the abdominal aorta. A hemostasis valve and special seal port allowed for simultaneous contrast injection and placement of the optical fiber. Cineangiograms of the distal aorta and both iliofemoral arteries were recorded. The radiopaque tip of the fiber was advanced 1 to 2 mm beyond the catheter. Because of the shape of the catheter, the fiber tip exited at an acute angle and abutted on the arterial wall. This ensured maximal delivery of energy to the arterial wall. In 7 dogs, multiple 1-second lasings were done starting from the distal end of the iliofemoral arteries. After each lasing, the catheter and the optical fiber were withdrawn 0.5 to 1 cm and lasing was repeated. A power of 1.5 W was used in the left iliofemoral artery, 2 W in the right iliofemoral artery and 2.5 W in the distal aorta. From these parameters energy flux was calculated to be 2,100 J/cm^2, 2,800 J/cm^2 and 3,500 J/cm^2, respectively. These parameters were selected because they were the minimum required to vaporize atherosclerotic plaque by direct fiber tissue contact.[1] One dog in which no lasing was performed served as a control for catheter and fiber trauma. Repeat cineangiography was obtained in each dog within 30 minutes of the last lasing. The control dog and 1 lased dog underwent repeat angiography and were killed after 1 hour. The other 6 dogs were allowed to recover, underwent repeat angiography and were killed at 2, 4, 7, 14, 30 and 60 days.

Atherosclerotic monkeys: Four male 3-year-old rhesus monkeys (*Macaca mulatta*) (6 to 8 kg) were fed an atherogenic diet since weaning (Bio Serve 1206). Anesthesia, catheterization and angiography were performed as previously described, except that a No. 5Fr thin-walled right Judkins catheter (Cordis Corp.) was used. All monkeys were allowed to recover. Angiography was repeated and the monkeys were killed at 7, 14, 40 and 60 days. Monkeys continued to receive the atherogenic diet after lasing until they were killed. The average serum cholesterol level before death was 392 mg/dl.

Gross inspection and histology: Immediately after death, the distal aorta and both iliofemoral arteries were removed, opened longitudinally and inspected. Tissues were fixed either in 10% neutral buffered formalin for light microscopy or in 2.5% gluteraldehyde in 0.2 *M* cacodylate buffer for scanning and transmission electron microscopy (SEM and TEM). Formalin-fixed tissues were dehydrated promptly through graded alcohols and embedded in paraffin blocks. From each artery, samples from lased areas were cut serially at a thickness of 5 μm and stained with hematoxylin-eosin or Verhoeff's elastic stain. Gluteraldehyde-fixed, 5-mm-long arterial segments containing a lased area were subjected to critical point drying in liquid CO_2, mounted on stubs and gold coated in a sputter coater for SEM. The intimal surface was examined with a JEOL 35 C electron microscope. The remaining samples were used for TEM. Lased areas were cut into 2-mm pieces, embedded in Spurr resin and thin-sectioned with a diamond knife. Sections were stained with uranyl acetate and lead citrate and viewed in a Phillips 300 electron microscope.

The incidence of angiographic evidence for arterial perforation in the left and right iliofemoral arteries was compared using Fisher's exact test. A p value <0.05 was considered significant.

Results

Lasing (Table I): *Mongrel dogs:* A total of 544 areas were irradiated in 21 arteries: left iliofemoral artery, 182; right iliofemoral artery, 176; and aorta, 186. No dog died after lasing.

Atherosclerotic monkeys: A total of 373 sites were irradiated in 12 arteries: left iliofemoral artery, 115; right iliofemoral artery, 100; and aorta, 158. No monkey died after lasing.

Angiographic findings (Table I): *Mongrel dogs:* Immediately after lasing, angiography showed perivascular contrast extravasation suggestive of arterial perforation in 3 of 7 dogs, once in the aorta and twice in the right iliofemoral artery. Thirty minutes later and before death no contrast extravasation was seen. Although no perforations were seen in left iliofemoral arteries, the incidence of perforation using 1.5 and 2 W in the left (0 of 7) and right (2 of 7) iliofemoral arteries, respectively, was not significantly different. Angiography never showed arterial spasm, dissection, aneurysmal dilatation or occlusion. In the control dog, no effect of fiber-catheter manipulation was seen.

Atherosclerotic monkeys: In contrast to dogs, catheter-induced spasm of the iliofemoral arteries was a frequent occurrence in monkeys before and after lasing. In monkey 2, fiber-catheter manipulation in the right iliofemoral artery caused severe spasm, resulting in

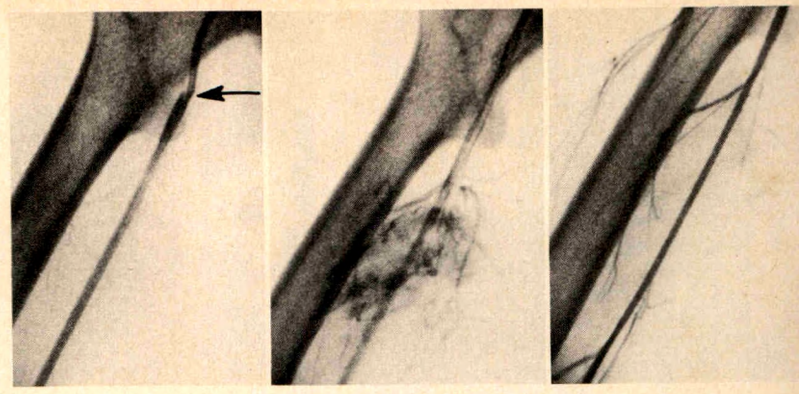

FIGURE 1. Left, angiogram of the right iliofemoral artery in a monkey before laser exposure. A right Judkins catheter was used to lase the arterial wall at an acute angle. Metal marker at fiber tip is pointed to the arterial wall (**arrow**). **Middle,** angiogram of the same artery immediately after lasing (2 W for 1 second). Extravasation of contrast material is seen. **Right,** angiogram 30 minutes after lasing showing patency of the vascular lumen with no further extravasation of contrast.The vessel walls are smooth.

perforation before lasing. All 4 monkeys underwent lasing, and angiography performed immediately after lasing showed perforation in 3 of 12 arteries (1 aorta and 2 right iliofemoral arteries). No angiographic evidence of perforation was seen on repeat angiograms recorded after 30 minutes (Fig. 1). Comparison of perforations while lasing with 1.5 and 2 W in the left (0 of 4) and right (2 of 4) iliofemoral arteries, respectively, was not significantly different. Angiography immediately after lasing never showed arterial dissection, aneurysmal dilatation or occlusion.

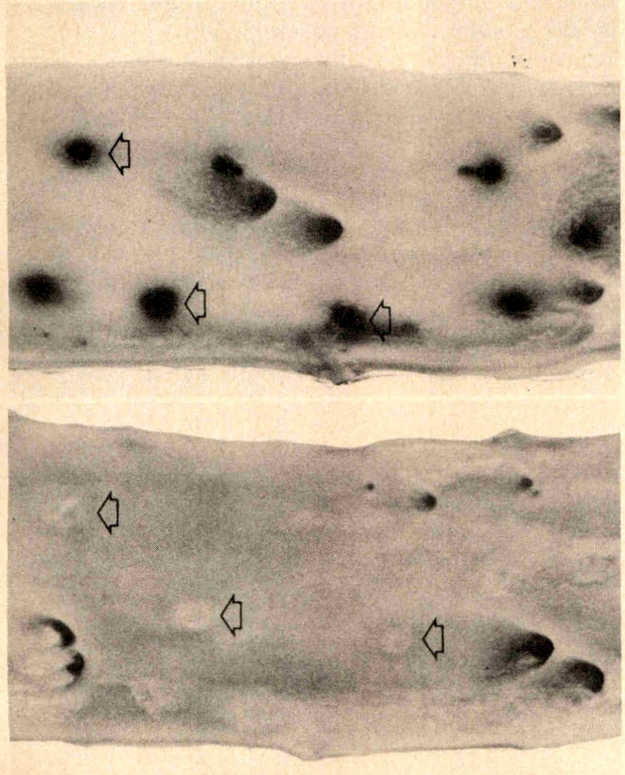

FIGURE 2. Top, gross appearance of a distal abdominal aorta from a dog at 1 week after lasing (2.5 W for 1 second). Numerous craters are present (**arrows**). There is no thrombus present. **Bottom,** gross appearance of a distal abdominal aorta from a dog 1 month after lasing (2.5 W for 1 second). The number of identifiable craters (**arrows**) is less than at 1 week. Those that are seen have a smooth, flat, white surface.

Angiography before 2 monkeys were killed at 14 and 60 days after lasing showed occlusive thrombus in 2 arteries at previously lased sites. In monkey 2, thrombosis was present in the right iliofemoral artery at the site of fiber-catheter perforation, which occurred before lasing. In monkey 4 thrombus occluded the distal end of the left femoral artery.

Gross inspection (Table I): *Mongrel dogs:* In lased dogs killed within 2 weeks, hematomas were present around both the aorta and iliofemoral arteries. In all lased dogs, raised, 1- to 2-mm reddish spots were present on the adventitial aspect of the arteries and corresponded to small craters on the intimal surface. The number of identifiable craters decreased and their depth diminished as the intervals between lasing and death increased (Fig. 2 and 3). The surface of older lesions were flat and had a glistening whitish appearance. These spots were not seen in the control dog.

Atherosclerotic monkeys: Perivascular hematomas surrounded the aorta and right iliofemoral artery in the monkey killed 7 days after lasing, but none were seen in those killed later. In all monkeys 1- to 2-mm reddish spots were present on the adventitial aspect of the arteries also corresponding with small intimal craters. Atherosclerosis was evenly distributed over the intimal surface. Similar to the dog arteries, fewer arterial craters could be identified as the interval after laser exposure increased (Fig. 3). Older lesions were flat and whitish in appearance. In monkeys 2 and 4, thrombus was seen in the 2 arteries that were angiographically occluded.

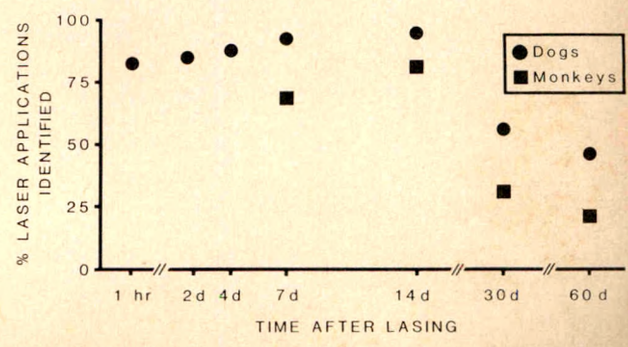

FIGURE 3. Percentage of arterial lased site identifiable by gross inspection of the intimal surface at different intervals after lasing in both dogs and monkeys. At 1 and 2 months, fewer craters are seen than at earlier periods.

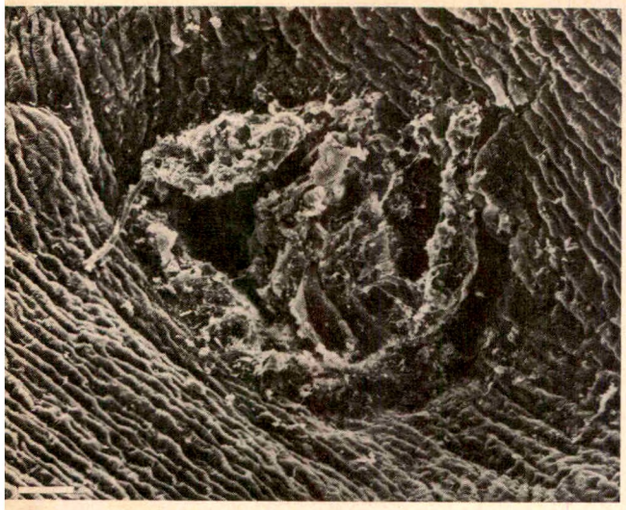

FIGURE 4. Scanning electron micrograph of the right iliofemoral artery from a dog killed 1 hour after lasing (2 W for 1 second). The crater site has sharply demarcated edges and is filled with coagulum of blood and cellular debris. Few platelets are seen. Magnification ×90, reduced by 30%. Bar = 100 μm.

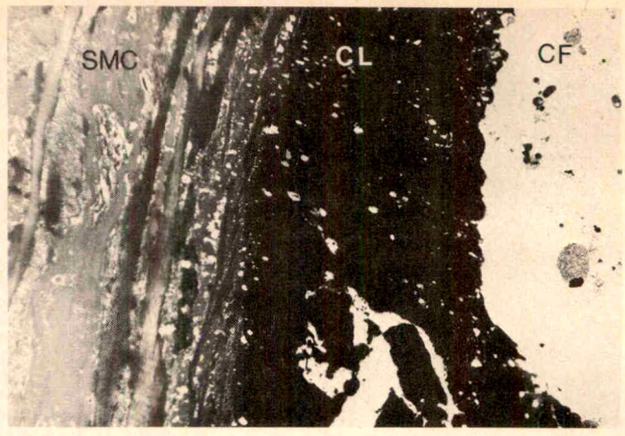

FIGURE 5. Transmission electron micrograph from the same artery as in Figure 4 showing the arterial surface 1 hour after lasing (2 W for 1 second). The surface is covered by a smooth carbonized layer (CL) seen here at the bottom of the crater overlying injured smooth muscle cells (SMC). Cellular fragments (CF) are seen loosely adherent to the lumen side of the arterial surface. Magnification ×6,600, reduced by 45%.

In monkey 1, a small thrombus was found in the distal right femoral artery at the site of lasing. This was not apparent on angiography.

Histology: *Mongrel dogs:* One hour after lasing, low-magnification SEM of the intimal surface revealed the laser impact area as a crater covered with a layer of coagulated elements with only a few adherent platelets (Fig. 4). Around the crater were occasional crenated red blood cells. Light microscopy showed that perforation of the arterial wall was sealed by thrombus. All craters were filled with a coagulum of blood and cellular debris that did not extend beyond the vascular lumen. On TEM, the coagulated edges of the crater were smooth and covered by a carbonized layer (Fig. 5). The material inside the crater was too denatured to be identified. In dogs killed at 2 and 4 days after lasing, TEM showed early healing. Healing was remarkable in that it evoked no polymorphonuclear leukocyte and only a weak mononuclear phagocyte response. By 7 days, the healing process was well under way with a low-grade cellular infiltrate consisting of smooth muscle cells and undifferentiated mesenchymal cells, probably fibroblasts. These cells were identified by TEM as cells containing prominent rough endoplasmic reticulum and absent cytoplasmic filaments with peripheral condensations. Reendothelialization was apparent at 7 and 14 days with elongated and proliferating endothelial cells partially covering the edges and surface of the craters. There was variability in the extent of reendothelialization among different craters in the same dog. Most craters were completely reendothelialized by 30 days (Fig. 6), and after 60 days all lased areas were healed.

Atherosclerotic monkeys: The arterial wall was characterized by a concentric intimal thickening mainly due to the presence of foam cells. At 7 and 14 days after lasing, the morphologic characteristic of the craters was similar to that observed in dogs. In monkeys, the mor-

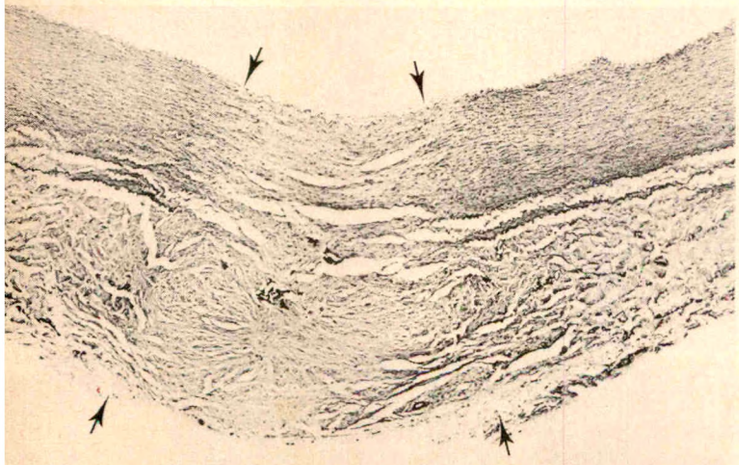

FIGURE 6. Light micrograph of a lased right iliofemoral artery from a dog killed 30 days after lasing (2 W for 1 second). **Arrows** point to lased regions. At the site of laser injury, intimal reendothelialization is complete; the media is hypocellular and the adventia appears thickened. Hematoxylin-eosin ×25, reduced by 35%.

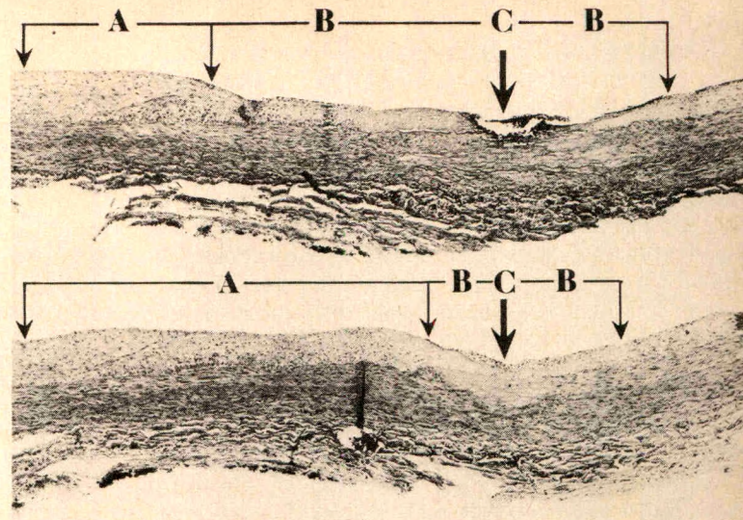

FIGURE 7. Light micrographs of hypercholesterolemic monkey aortas killed at 7 days (**top**) and 30 days (**bottom**) after lasing (2.5 W for 1 second). Zone A is the surrounding nonlased plaque; zone B is the plaque bordering the crater; zone C is the crater made by lasing. **Top,** the crater at 7 days is clearly visible with charred edges and a lumen filled with a coagulum of cellular debris. The bordering zone B is characterized by thinning of the intima, whereas the surrounding zone A shows the intimal thickening typical of this atherosclerotic model. Hematoxylin-eosin ×25, reduced by 39%. **Bottom,** the crater at 1 month is reendothelialized and hypocellular. The reformed arterial intima at the crater site as well as at the adjacent zone B is thinner than that in zone A. Hematoxylin-eosin ×25, reduced by 39%.

phologic configuration of the area adjacent to the crater was of particular interest. In these hypercholesterolemic monkeys, the intimal thickening of the atherosclerotic plaque was thinned adjacent to the crater (Fig. 7). This thinning persisted for at least 60 days and was a result of a decreased number of intimal cells. For at least 60 days, lased areas showed only minimal or no reappearance of foam cells or cholesterol deposits. At 30 and 60 days after lasing, the craters showed reendothelialization (Fig. 8).

Discussion

Laser irradiation of both muscular and elastic arteries in normal and atherosclerotic animals lead to the formation of craters that heal in 30 to 60 days. The healing process was remarkable for the following reasons: (1) Few platelets were seen near or at the lased site. (2) Injury induced by lasing did not evoke a strong inflammatory reaction. (3) Healing involved reendothelialization and participation of both smooth muscle cells and other mesenchymal cells, probably fibroblasts. The absence of platelet adhesion is especially encouraging and may explain the low incidence of occlusive thrombosis after lasing. However, the coagulated debris that filled the crater together with the formation of an extravascular hematoma appeared adequate to prevent serious leakage from the arterial lumen. The paucity of inflammatory cells involved in the healing process indicates an unusual response to injury that either evokes little chemotactic activity or inhibits inflammatory cell adherence and migration.[14] Although macrophages were not particularly prominent, their numbers appeared sufficient for debridement and possibly for promoting smooth muscle cell and fibroblast participation in repair through growth factor production.[15] Because fibroblasts are not normally a component of adult intima or media, it is presumed that they migrated into the crater from the adventia. Reendothelialization was observed to occur at various rates, but was usually completed by 30 days.

Laser radiation of atherosclerotic arteries in hypercholesterolemic monkeys did not accelerate atherosclerosis over the period studied. In these monkeys, the intima at lased sites and at the bordering areas actually appeared thinner than the surrounding nonlased intima, suggesting a persistent effect. This response to injury contrasts with reactions to other types of arterial injury such as balloon endothelial stripping, which leads to an acceleration of atherosclerosis.[7–11]

These results are encouraging and demonstrate the feasibility of lasing by the transluminal approach in the presence of blood. Extrapolation of these findings in animals to the clinical setting can be made only with caution. The pathology of human atherosclerosis is different from that in the experimental animal.[16] However, the fact that the healing process was similar in muscular and elastic arteries of normal dogs and atherosclerotic monkeys suggests that responses of

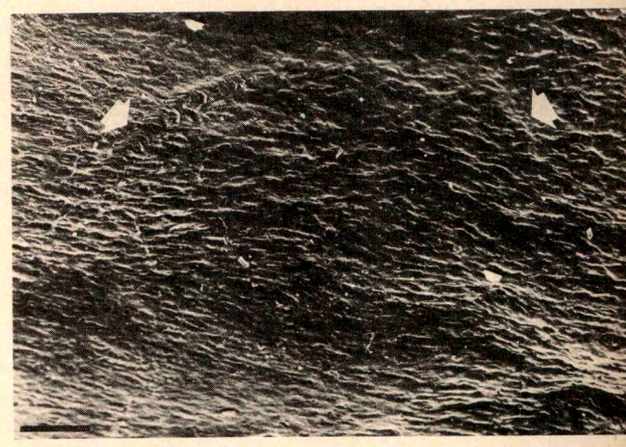

FIGURE 8. Scanning electron micrograph of the left iliofemoral artery from a monkey killed 60 days after lasing (1.5 W for 1 second). The lased site is reendothelialized and appears as a shallow depression (**arrows**) on the intimal surface of the artery. Magnification ×80, reduced by 49%. Bar = 100 μm.

different arterial walls to laser injury may be similar in other species.

Despite maximal wall damage, no dissection, occlusive thrombosis or aneurysm formation was seen in any of the normal lased dog arteries. In a previous study we found a high incidence of thrombosis after lasing, but these studies used surgically exposed arteries, and lasing was done in air adjacent to the arteriotomy.[12] A transluminal catheter approach to lasing avoids local surgical trauma which can contribute to thrombosis. Occlusive thrombosis was an infrequent event and was present in only 2 small branches of the femoral artery. Spasm or fiber-catheter trauma could have contributed to thrombus formation. In atherosclerotic pigs, the healing process of aortas irradiated with a CO_2 laser adjacent to an arteriotomy was similar to that observed in dogs and atherosclerotic monkeys.[13] That study, however, showed considerable platelet deposition, which may have been related to either the CO_2 laser, lasing in air in the absence of saline solution or blood, or the adjacent arteriotomy.

Aneurysm formation was not observed in our experiments; however, Lee et al[6] reported this complication in rabbits. In that study aneurysm formation might have been attributed to a larger and stiffer 400-μm core silica optical fiber and to rabbits having thinner arterial walls than dogs or monkeys.

Validation of Instantaneous Pressure Gradients Measured by Continuous-Wave Doppler in Experimentally Induced Aortic Stenosis

MARK J. CALLAHAN, MD, A. JAMIL TAJIK, MD, QIAN SU-FAN, MD, and ALFRED A. BOVE, MD

The relation between catheter-measured and Doppler-derived aortic pressure gradients was examined in 8 open-chest dogs. A snare was placed around the proximal ascending aorta and adjusted to provide a wide range of gradient to left ventricular (LV) outflow. A continuous-wave Doppler transducer was placed above the level of the obstruction and angled to optimize the audio and spectral signals. Pressure tip transducer catheters recorded LV and ascending aortic pressures simultaneously with the Doppler signal. In 120 randomly selected sinus beats, Doppler-derived maximal gradient correlated well with maximal instantaneous catheter gradient from 4 to 179 mm Hg ($r = 0.99$). Mean gradients also were closely related ($r = 0.98$). For gradients above 100 mm Hg, the correlation remained good ($r = 0.98$), but for gradients below 50 mm Hg, the correlation was not as precise ($r = 0.81$). All 120 cycles were digitized at 10-ms intervals to examine the correspondence between the Doppler and catheter data throughout systole. For the 2,742 pairs of points so obtained, the correlation was excellent ($r = 0.95$). The close relation between Doppler-derived pressure gradient and that measured simultaneously by catheterization provides further validation of the use of continuous-wave Doppler in the assessment of aortic stenosis, not only at maximal gradient, but throughout the period of LV ejection.

(Am J Cardiol 1985;56:989–993)

Doppler echocardiography has an important role in the noninvasive assessment of valvular heart disease. Continuous-wave Doppler has been used to measure the increased blood velocity across the aortic valve in patients with aortic stenosis (AS).[1–4] The peak aortic flow velocity is used to derive the pressure gradient across the aortic valve by means of a simplified version of the Bernoulli equation.[2] Although initial studies reported a good correlation between aortic valve gradient at catheterization and that estimated by Doppler, uncertainties remain concerning the validity of this simplification.

This study was undertaken to confirm, in a controlled experimental environment, the overall correlation of Doppler and catheterization gradients (maximum, mean and peak-to-peak) and also to investigate the instantaneous relation between aortic flow velocity and pressure gradient throughout the cardiac cycle.

Methods

Eight mongrel dogs, mean weight 19 kg (range 17 to 22.5), were anesthetized with intramuscular Innovar® (0.25 ml/kg), followed by intravenous sodium pentobarbital (30 mg/kg). The dogs were intubated and ventilated with a standard volume respirator. The heart and ascending aorta were exposed through a right thoracotomy and dissected free of adventitial fat up to the level of the arch. A Millar pressure tip transducer catheter (No. 7Fr) was inserted into the left ventricle by apical puncture. This catheter included a port that allowed injection of indocyanine green dye for cardiac output determinations. A second Millar (7Fr) catheter was introduced into the ascending aorta by carotid artery cutdown. This catheter could record an intraaortic phonocardiogram. The left femoral artery was cannulated for withdrawal of arterial blood during cardiac output determinations. A snare made of 2 mm of polyethylene tubing containing a short length of umbilical tape was placed around the proximal ascending aorta. This provided controlled, adjustable levels of obstruction to left ventricular (LV) outflow (Fig. 1).

Continuous-wave Doppler techniques: Doppler information was obtained by using a nonimaging transducer incorporated into an Irex 3-B system. The transducer was placed in a surgical glove containing ultrasonic gel and was hand-held on the ascending aorta close to the arch. Care was taken to ensure that the transducer was positioned with light pressure and angled to obtain a Doppler signal of maximal velocity while preserving a clear envelope. At each level of gradient, this angle was optimized by fine adjustment of the tilt of the hand-held transducer, guided only by the quality of the audio and spectral signals. No echocardiographic imaging was performed during the studies.

The Irex 3-B instrument had been modified by the addition of a DC coupler unit, which allowed simultaneous recording of pressure traces and Doppler spectral output on the 7-inch

TABLE I Results

Parameter	r	SEE	n	Equation
Maximal Doppler vs maximal catheter	0.99	5.2	120	y = 0.98x + 0.7
Gradient > 100 mm Hg	0.98	4.6	17	y = 1.1x − 8.6
Gradient < 100 mm Hg	0.98	5.1	103	y = 0.95x + 2.1
Gradient <50 mm Hg	0.81	7.1	50	y = 0.7x + 10.6
Cardiac output >1.5 liters/min	0.97	8.0	78	y = 0.96x + 2.4
Cardiac output <1.5 liters/min	0.99	4.8	42	y = 0.94x + 4.9
Mean Doppler vs mean catheter	0.98	4.3	120	y = 0.94x + 2.9
Maximal Doppler vs peak-to-peak catheter	0.95	10.5	120	y = 0.89x + 1.8
Doppler-catheter (10-ms intervals)	0.95	9.4	2742	

SEE = standard error of the estimate.

strip-chart recorder. The Doppler spectral output and Millar pressure traces were recorded together with the lead II electrocardiogram at 100 mm/s. Cardiac output was measured by injecting indocyanine green in the left ventricle and sampling in the femoral artery.

The catheters were calibrated before use. Baseline records were then obtained at 0 gradient. The snare was next tightened to provide a gradient to aortic outflow. Once the dog had equilibrated at this gradient, new recordings were obtained. This was repeated for each level of obstruction created.

To derive gradient from the Doppler velocity, a simplification of the Bernoulli relationship was used: $P = 4V^2$, where P = pressure gradient at a specified time and V = simultaneous blood velocity. Since the transducer was angled to obtain maximum velocities, we assumed that the beam was nearly parallel to the jet. Furthermore, since the true direction of the aortic jet could not be known, we did not correct for possible angles between the Doppler beam and the jet.

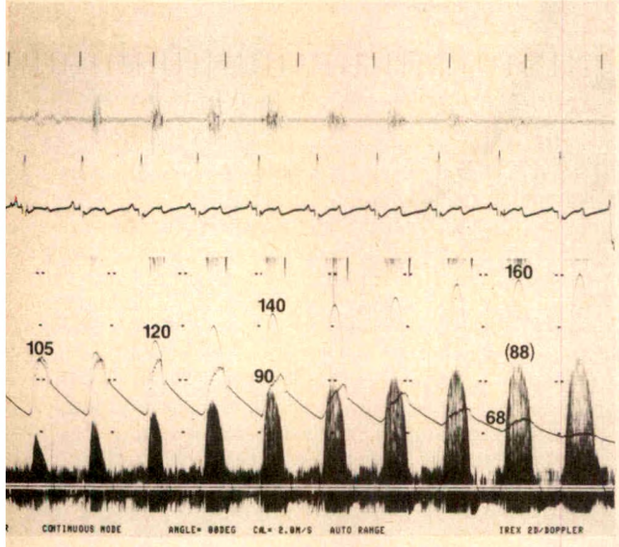

FIGURE 1. Record obtained at a paper speed of 25 mm/s during progressive tightening of the ascending aortic snare. **Vertical dots** are the Doppler velocity calibration in 2-m/s intervals. Peak left ventricular (LV) systolic pressures are recorded above the LV traces. Simultaneous aortic pressures are recorded next to the aortic traces. The maximal Doppler-derived gradient for the next to last cycle is recorded in parentheses next to the aortic pressure trace. Note the concurrent increase in both the catheter gradient and the Doppler velocity, on a beat-to-beat basis. At the start of the recording, peak LV systolic pressure is 105 mm Hg with a minimal gradient. At this point, the peak Doppler velocity is 1.7 m/s, which yields a maximal instantaneous gradient of 11 mm Hg. The snare is then tightened. Near the end of the recording, the maximal instantaneous catheter gradient is 92 mm Hg, with a peak LV systolic pressure of 160 mm Hg. The maximal Doppler velocity at this time is 4.7 m/s. This yields a maximal gradient of 88 mm Hg.

Data analysis: To determine the instantaneous relation between Doppler and catheterization data, selected beats were measured using a computer graphic analysis system consisting of a digitizing table (Houston Instruments) and a PDP 11/34 digital computer (Digital Computer Corp.). LV and ascending aortic pressure tracings were outlined, as was the envelope of the Doppler spectral signal. Data were acquired at 10-ms intervals throughout the LV ejection period. At each 10-ms interval, Doppler velocity was used to derive the pressure gradient by means of the simplified Bernoulli relation discussed previously. Mean Doppler gradient was calculated from the average of these gradients through the ejection period.

Linear regression analysis was done for the following pairs of data: (1) mean gradient (Doppler) vs mean gradient (catheter); (2) maximal pressure gradient (Doppler) vs maximal instantaneous gradient (catheter); (3) maximal pressure gradient (Doppler) vs peak-to-peak systolic gradient (catheter); (4) simultaneous Doppler-derived and catheter pressure gradients at 10-m/s intervals throughout the LV ejection period; and (5) ratio of time to peak Doppler velocity/LV ejection time vs maximal instantaneous and mean catheter gradient.

To determine where the outline of the Doppler signal should be traced, a random sample of 25 cycles was selected. Outlines were traced in 3 positions for each cycle: at the outer, "fuzzy" edge of the Doppler signal; through the center of the dark Doppler envelope; and at the inner border of the dark Doppler envelope.

Results

Satisfactory data were obtained from all dogs (Table I). Analysis was performed on 120 sinus beats selected at random from the 8 dogs. Beats with an indistinct or incomplete Doppler envelope were excluded, as were ectopic and postectopic beats. Cycles displaying pulsus alternans were included. The back-scattered Doppler signal recorded during indocyanine green dye injection was so markedly enhanced as to saturate the amplifier in the Doppler instrument. Therefore, no cycles recorded during or immediately after dye injection were included in this analysis.

Linear regression analysis of the mean Doppler-catheterization correlation (r) for the 25 cycles at 3 levels through the Doppler envelope yielded the following data (Fig. 2): outer edge: r = 0.96, standard error of the estimate (SEE) = 8.9 mm Hg; center of the dark envelope: r = 0.99, SEE = 4.4 mm Hg; inner border of the dark envelope: r = 0.99, SEE = 5.4 mm Hg. On this basis, we used the center of the dark Doppler envelope for all subsequent data analysis.

The maximal catheter gradients ranged from 4 to 179 mm Hg (mean 62.3). The Doppler peak velocity ranged from 1.1 to 6.5 m/s (mean 3.8). The cardiac output

ranged from 1.0 to 2.6 liters/min. The calculated aortic valve areas ranged from 0.1 to 2.0 cm^2.

The maximal instantaneous catheter gradient for each beat was compared with the Doppler-derived maximal gradient. The correlation was 0.99, with an SEE of 5.2 mm Hg (Fig. 3). The peak-to-peak catheter gradient correlated less well with the Doppler-derived maximal gradient and the SEE was greater: (r = 0.95, SEE = 10.5 mm Hg). For each beat analyzed, mean catheter gradients were compared with Doppler-derived mean gradients: r = 0.98, SEE = 4.3 mm Hg.

Separate linear regression analysis was performed for peak catheter gradients greater than and less than 100 mm Hg. For peak gradients greater than 100 mm Hg, r = 0.98, SEE = 4.6 mm Hg. For peak gradients less than 100 mm Hg, r = 0.98, SEE = 5.1 mm Hg. For the 50 points obtained at catheter gradients less than 50 mm Hg, the correlation was not as precise: r = 0.81, SEE = 7.1 mm Hg.

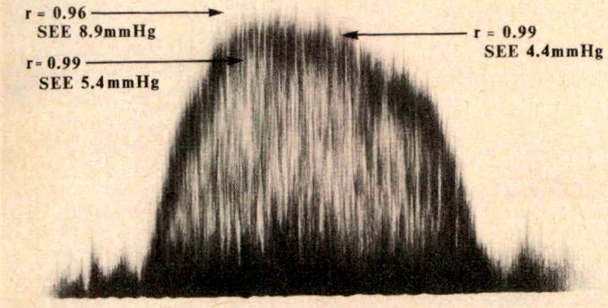

FIGURE 2. Schematic drawing of a Doppler signal. A dark "envelope" is at the outer margin of the signal. Above this envelope is a "fringe," which may represent noise. The 25 test records discussed in the Methods section were traced at the levels indicated in the diagram: outer margin of the Doppler signal, r = 0.96, standard error of the estimate (SEE) = 8.9 mm Hg; center of the dark envelope, r = 0.99, SEE = 4.4 mm Hg; inner edge of the dark Doppler envelope, r = 0.99, SEE = 5.4 mm Hg.

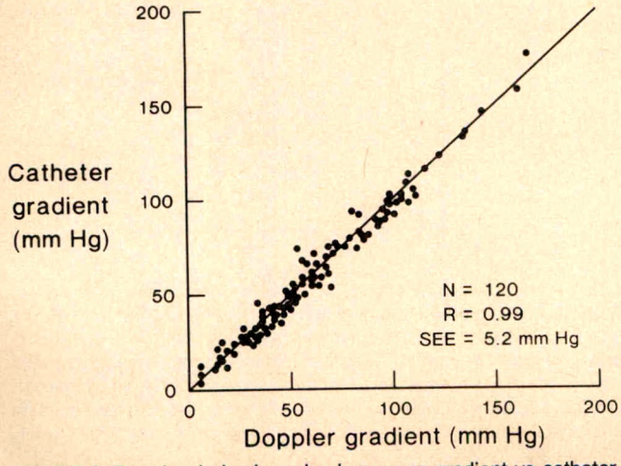

FIGURE 3. Doppler-derived maximal pressure gradient vs catheter-measured maximal instantaneous pressure gradient for all 120 points.

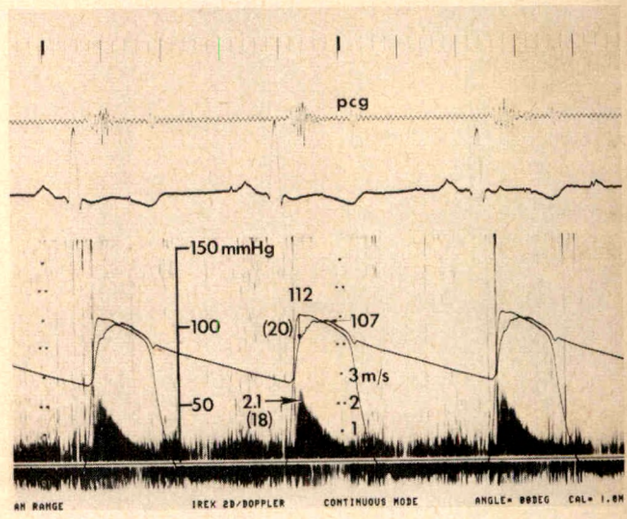
To examine the effect of cardiac output on the correlation, separate linear regression was performed on the maximal pressure gradient determined by Doppler and catheter for cardiac outputs greater than and less than 1.5 liters/min. For cardiac outputs greater than 1.5 liters/min, r = 0.97, SEE = 8 mm Hg; for those less than 1.5 liters/min, r = 0.99, SEE = 4.8 mm Hg.

The points obtained from digitization of the Doppler and catheterization data at 10-ms intervals were compared throughout the period of LV ejection. For the 2,742 points obtained from the 120 beats analyzed, the correlation was excellent (r = 0.95, SEE = 9.4 mm Hg) (Fig. 4 to 7).

No significant correlation (r = −0.01) was observed between the ratio of time to maximum Doppler veloc-



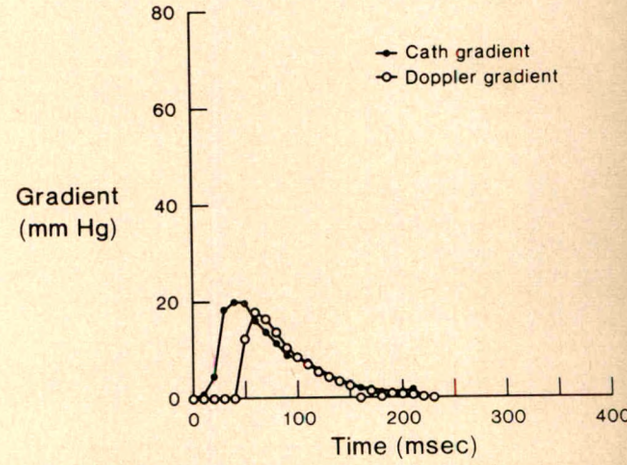


FIGURE 4. Top, record obtained at low gradient. The peak left ventricular systolic pressure (112 mm Hg) is displayed above the left ventricular pressure trace. The maximal instantaneous catheter gradient (20 mm Hg) is listed in parentheses next to the **vertical arrow.** The peak Doppler velocity (2.1 m/s) is displayed next to the Doppler signal. The gradient calculated from this (18 mm Hg) is listed in parentheses underneath the velocity. **Vertical dots** are the Doppler velocity calibration in 1-m/s intervals. Peak aortic pressure (107 mm Hg) is indicated by **thin horizontal arrow.** Note the discrepancy between the maximal instantaneous gradient (20 mm Hg) and the peak-to-peak catheter gradient (5 mm Hg). pcg = phonocardiogram. **Bottom,** digitized pressure gradient data obtained from the above record. Note the delay in initial upstroke seen in the Doppler trace.

ity/LV ejection time and maximal pressure gradient. Similarly, no significant correlation (r = 0.08) was found between the LV ejection time and peak pressure gradient.

Discussion

This study was undertaken in an idealized setting in order to examine the details of the Doppler-catheterization correlation freed from the technical limitations inherent in a clinical trial. Our findings identified a close correlation between Doppler-derived maximal gradient and maximal instantaneous catheter gradient. The relation was linear and remained so at the extremes of gradient, with somewhat less precise correlation observed for gradients less than 50 mm Hg. Among the explanations for this observation is that the velocity profile across mildly stenotic valves is less flat than for more severe stenoses, resulting in greater errors from neglecting the contribution of viscous friction to the gradient calculation. In addition, the slight error introduced by neglecting the prestenotic velocity may be more appreciable at low levels of gradient. At gradients greater than 120 mm Hg, the Doppler signal continued to reflect accurately the true pressure drop across the ascending aorta.

The correlation of mean gradients was essentially similar to that noted for maximal instantaneous gradients. This suggests that the relation between Doppler velocity and catheterization data applies not only at maximal gradient, but also during the entire period of ejection.

The point-to-point correlations were good, but appeared to be somewhat affected by a brief delay often seen in the Doppler record at the beginning and end of

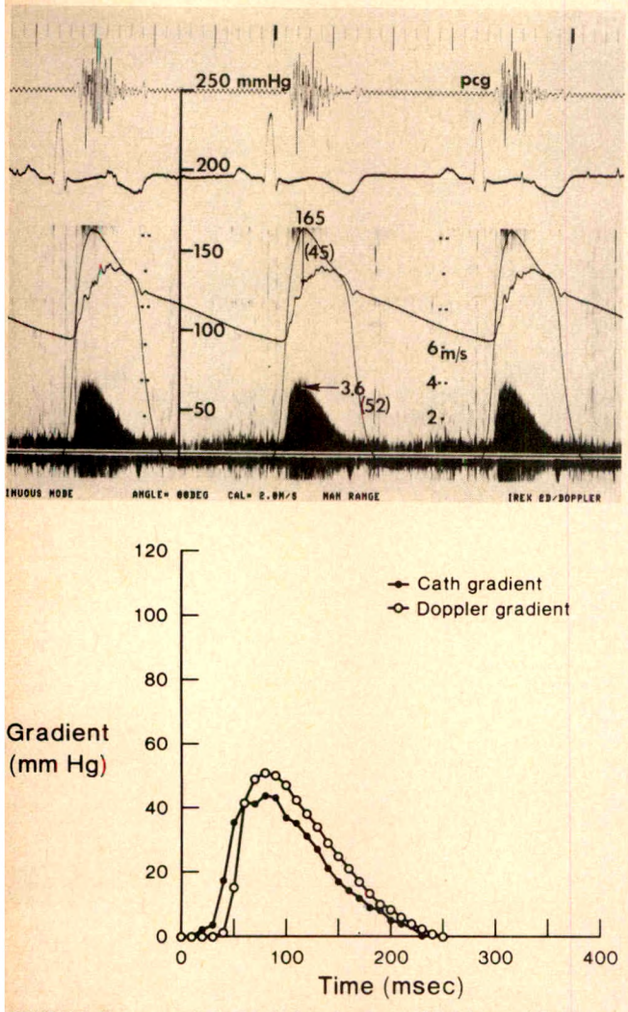

FIGURE 5. Top, record obtained at moderate gradient. Legend for Figure 4 provides explanation of the record. **Vertical dots** representing the Doppler velocity calibration are in 2-m/s intervals. The peak systolic left ventricular pressure was 165 mm Hg. Maximal instantaneous pressure gradient was 45 mm Hg. Maximal Doppler velocity was 3.6 m/s, yielding a calculated gradient of 52 mm Hg. **Bottom,** digitized pressure gradient data obtained from the above record. Doppler slightly overestimates the gradient in this instance.

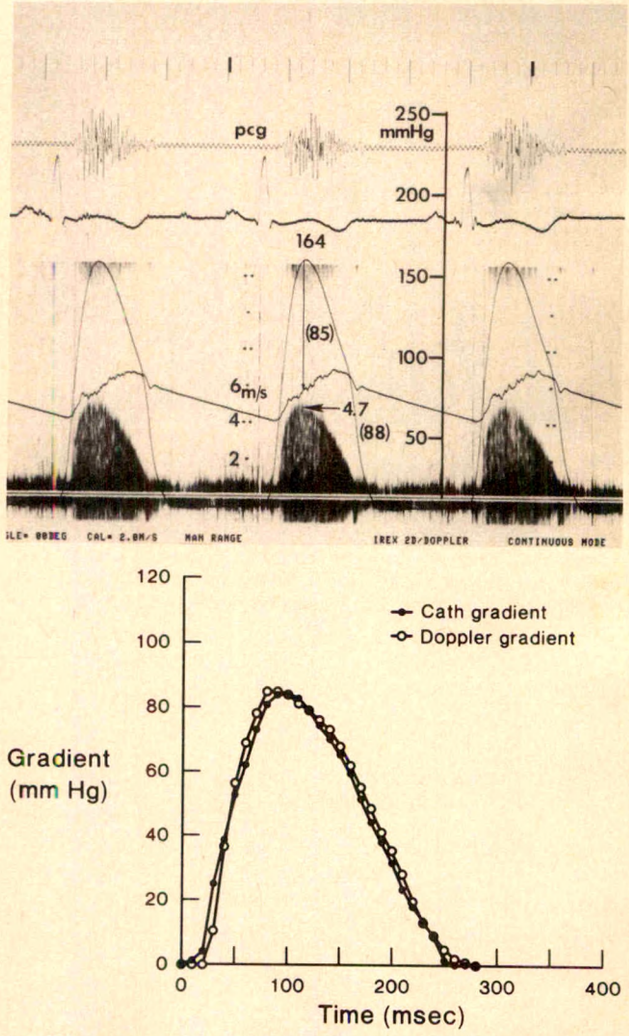

FIGURE 6. Top, record obtained at high gradient. Legend for Figure 4 provides explanation of the record. Peak systolic left ventricular pressure was 164 mm Hg. Maximal instantaneous pressure gradient was 85 mm Hg. Maximal Doppler velocity was 4.7 m/s, yielding a calculated gradient of 88 mm Hg. **Bottom,** digitized pressure gradient data obtained from the above record. The 2 curves correspond closely throughout systole.

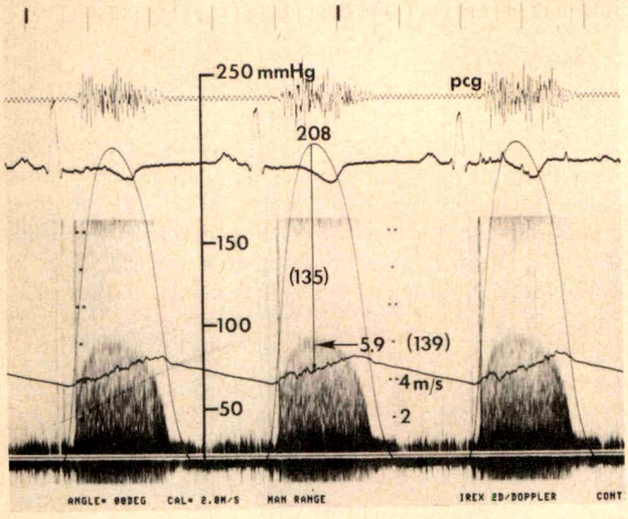

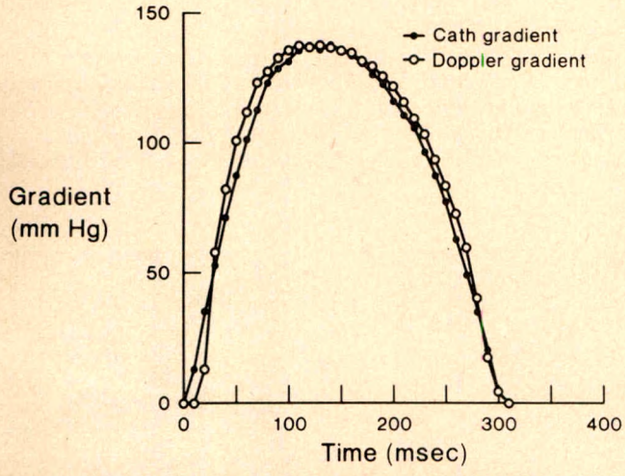

FIGURE 7. Top, record obtained at a critical gradient. See Figure 4 for an explanation of the record. Peak systolic LV pressure was 208 mm Hg. Maximal instantaneous pressure gradient was 135 mm Hg. Maximal Doppler velocity was 5.9 m/s, yielding a calculated gradient of 139 mm Hg. **Bottom,** digitized pressure gradient data obtained from the above record. The 2 curves correspond very closely and are essentially superimposed.

LV ejection, times when the pressure gradient was changing most rapidly. In a rapidly changing hydrodynamic system, the pressure waveform precedes the velocity pulse in time. In addition, the Chirp Z spectral analysis algorithm incorporated into the Doppler instrument used in this study introduces a small delay in the display in the returning Doppler signal. Neglecting the contribution of flow acceleration when deriving pressure gradients from the modified Bernoulli equation would also be expected to introduce a delay in the Doppler-calculated pressure curve.[5]

Despite these minor points, the close Doppler-catheterization correlation observed within the period of LV ejection strongly suggests that the Doppler signal accurately represents pressure gradients, from beat to beat and throughout LV ejection. Further, this correlation persists over a wide range of gradients.

The correlation between Doppler-derived maximal gradient and peak-to-peak systolic gradient determined at catheterization was good, but not as close as for the other variables discussed above. This is not surprising, because the Doppler signal measures instantaneous changes in blood velocity and would be expected to correspond most closely with instantaneous measurements of pressure gradient and not with nonsimultaneous points as represented by the expression of peak-to-peak gradient. Indeed, the use of the convenient catheterization laboratory measurement of peak-to-peak systolic gradient for correlation with Doppler pressure gradient may lead to the erroneous conclusion that the Doppler technique overestimates the severity of AS.

The lack of significant correlation between maximal and mean catheter gradient and the ratio of time to maximal Doppler velocity/LV ejection time contradicts previous clinical work.[5] This finding may be explained by the physiologic differences between acute LV outflow obstruction and the chronic obstruction observed in clinical situations. However, in recent studies in our clinical laboratory, similar observations regarding this lack of significant correlation have been independently confirmed.[6]

This study shows that accurate continuous-wave Doppler assessment of pressure gradients may be made solely by optimizing the audio and spectral signals, without incorporating angle correction. In this experimental model of aortic outflow obstruction, the Doppler-derived gradients correlated closely with catheter gradients throughout systole and across a wide range of obstruction.

Dynamic Nature of Coronary Collateral Blood Flow

DAVID S. KRAMER, MD
JOHN MICHAEL CRILEY, MD

How coronary collateral blood flow is "turned on" and "turned off" is not known. Moreover, the rapidity with which coronary blood flow can become evident after total occlusion of a coronary artery and then become nondetectable again after resolution of the coronary artery occlusion has been reported infrequently.[1,2] Recent studies[3,4] showed that collateral channel filling may improve within 60 to 90 seconds after sudden coronary occlusion by an angioplasty balloon in certain patients with severe coronary stenosis. This report demonstrates the dynamic nature of coronary collateral flow. Collateral blood flow appeared immediately after total occlusion of a coronary artery. After transluminal disobliteration,[5] anterograde blood flow returned and collateral blood flow was no longer seen.

From the Department of Medicine, Division of Cardiology, UCLA School of Medicine, Harbor-UCLA Medical Center, Torrance, California. Manuscript received March 25, 1985; revised manuscript received May 29, 1985, accepted May 30, 1985.

A 63-year-old man with a 5-month history of poorly controlled angina pectoris underwent left-sided cardiac catheterization and coronary arteriography. Left ventriculography revealed moderate apical hypokinesia with a normal ejection fraction of 67%. The initial coronary arteriographic injections (Fig. 1) revealed high-grade lesions in all of the proximal major branches of both coronary arteries. No left-to-right collateral filling was noted (Fig. 1B). Right coronary arteriography (Fig. 1A) revealed multiple lesions, including greater than 99% narrowing near its ostium with brisk distal flow. Subsequent injections of the right coronary artery after the onset of 5/10 chest pain revealed poor distal filling and evidence of reciprocating flow of unopacified blood from the distal artery. The chest pain was not responsive to sublingual or intracoronary nitroglycerin administration. Subsequently,

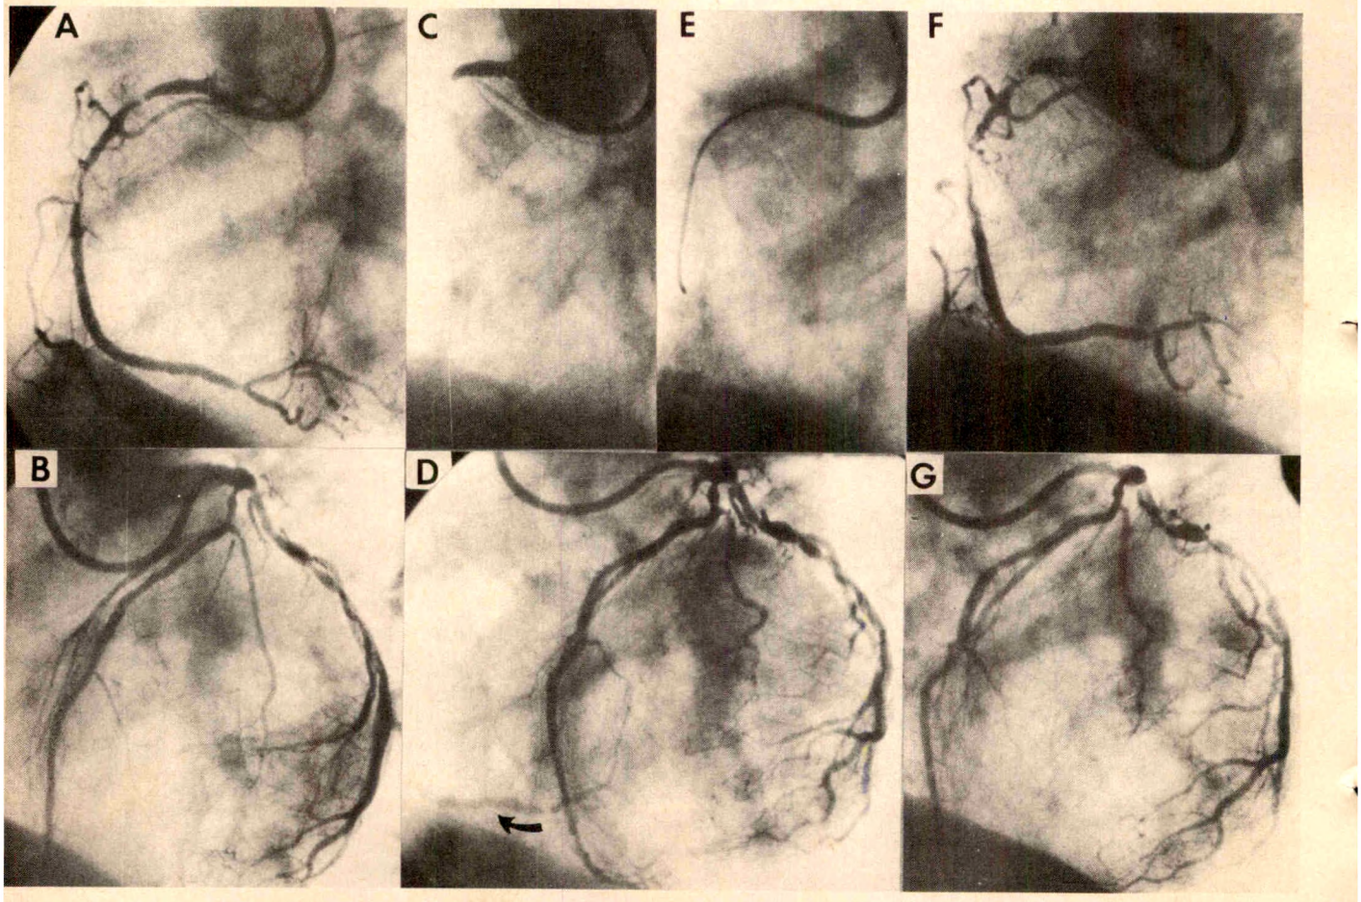

FIGURE 1. Selective injections of the right (**top**) and left (**bottom**) coronary arteries in the left anterior oblique projection. The injections are arranged in chronologic order before (**A** and **B**), during (**C, D** and **E**) and after (**F** and **G**) total occlusion of the proximal right coronary artery, and reveal collateral flow (**arrow, D**) while the right coronary artery is occluded.

injections revealed progression to total occlusion of the proximal vessel and no distal filling (Fig. 1C). An injection of the left coronary artery revealed multiple obstructions, as had been previously seen, but left-to-right collateral flow, which filled the right coronary artery, was noted (Fig. 1D). A guidewire was then passed through the occluded right coronary artery lesion and a catheter was passed over the wire but could not be advanced past the lesion (Fig. 1E). Subsequent injection of contrast medium revealed opening of the proximal right coronary artery obstruction with return of anterograde flow through the right coronary artery (Fig. 1F). A repeat left coronary arteriogram revealed disappearance of left-to-right collaterals (Fig. 1G). The chest pain was completely relieved concurrent with the restoration of flow through the right coronary artery, approximately 20 minutes after the onset of pain and the demonstration of sluggish flow in the right coronary artery. A 12-lead electrocardiogram at the completion of the catheterization study was unchanged from that before catheterization.

In the coronary care unit, the patient received full-dose heparin and antiplatelet therapy. He had a small increase in serum creatine kinase levels, to 321 mU/ml (normal 45 to 235 mU/ml) with 14.8% MB fraction. He later underwent successful coronary artery bypass surgery.

The ineffectiveness of sublingual and intracoronary nitroglycerin on the total occlusion of the proximal right coronary artery in our patient suggested that the occlusion may not have been a result of coronary artery spasm but may have been the result of either a platelet plug or an acute intracoronary thrombotic occlusion, which are known complications of coronary angiography.[6]

Pacemaker Malfunction After Nitrous Oxide Anesthesia

GERVASIO A. LAMAS, MD
GEORGE S. REBECCA, MD
NINA S. BRAUNWALD, MD
ELLIOTT M. ANTMAN, MD

Entrapment of gas in the pacemaker pocket has been reported.[1,2] Pacemaker malfunction in those studies was a result of loss of anodal contact, and presented with small amplitude, variable amplitude or absent pacing spikes with loss of ventricular capture. We report a patient in whom pacemaker malfunction was caused by the presence of an anesthetic gas within the pacemaker pocket itself.

An 89-year-old woman was hospitalized after she was found lying on the floor of her home. An evaluation revealed both a fractured hip and complete heart block. A Telectronics 5281 (Optima MPT; VVI, M) generator and a unipolar Medtronic 4011-58 electrode were implanted. The prepectoral pocket was flushed with antibiotic solution before closing. The generator exhibited normal (VVI) function for 24 hours after implantation. The day after implantation the patient underwent total hip replacement with use of nitrous oxide and narcotic anesthesia. While in the operating room, intermittent failure to pace was noted. Examination of the pacemaker pocket revealed marked crepitus and distention owing to gas in the prepectoral pocket. Agitation of the pacemaker pocket with motion of the generator led to intermittent appearance of ventricular spikes and ventricular capture. Positioning a magnet over the generator led to VOO pacing at a rate of 99 beats/min without further loss of capture. The gas was manually expressed to the perimeters of the pocket and loss of ventricular capture became less frequent. The next day, crepitus in the prepectoral pocket could no longer be demonstrated, and motion of the generator did not lead to loss of ventricular capture.

Entrapment of gas in the pacer pocket with resultant pacer malfunction owing to interruption of anodal contact has been described.[1,2] In both previous cases, the involved gas was air that had not been effectively evacuated from the pacemaker pocket during the implant procedure. In the present case, the entrapped gas was a mixture of nitrous oxide and air.

Nitrous oxide is an inorganic anesthetic gas that is poorly soluble in water. It diffuses readily into the body's air-containing structures until it approaches equilibrium with the partial pressure of the inspired gas mixture. This phenomemon can lead to a marked volume increase of any air pockets, such as a pneumothorax, or even of intracranial air after pneumoencephalography.[3,4] In the present case, despite air evacuation with antibiotic solution before closure of the prepectoral pocket, a small amount of air remained entrapped in the generator pocket. In general, this small amount of air should have no clinical significance. However, nitrous oxide diffused into the pocket from the blood to reach an equilibrium with its partial pressure in the inspired gas mixture. This caused an expansion of the gas in the pocket, which led to loss of anodal contact and pacing system malfunction.

Angiographic Diagnosis of Coronary Sinus Ostium Atresia

SCOTT B. YEAGER, MD
ARPY A. BALIAN, MD
ROBERT A. GUSTAFSON, MD
WILLIAM A. NEAL, MD

Atresia of the ostium of the coronary sinus is a rare cardiac anomaly that has been diagnosed exclusively at necropsy.[1]

Cardiac catheterization of a term female infant confirmed the clinical and 2-dimensional echocardiographic diagnosis of pulmonary atresia with intact ventricular septum. Right ventricular angiography showed myocardial sinusoids with retrograde filling of the coronary arteries. The coronary veins drained to the left superior vena cava (SVC). There was no direct coronary venous drainage to either atrium. Selective injection into the left SVC (Fig. 1) confirmed the diagnosis of atresia of the coronary sinus ostium. The patient survived a palliative shunt but died of intraoperative arrhythmias at 3 months of age after attempted pulmonary valvotomy. Autopsy was refused.

A recent review by Gerlis et al[1] reported 15 cases of coronary sinus ostium atresia and persistent left SVC, all discovered at necropsy. Six cases had associated cardiovascular anomalies: most of the remainder were asymptomatic adults. We believe that the infant described herein is the first in whom coronary sinus ostium atresia was diagnosed using angiography and the first to have associated pulmonary atresia with intact ventricular septum.

On retrospective review, the echocardiogram showed the small left SVC but not the coronary sinus or coronary sinus ostium. Therefore, the only echocardiographic clue to the diagnosis was the absence of the dilated coronary sinus usually associated with a left SVC. Although not performed in our infant, Doppler interogation of the left SVC should reveal reversal of the usual direction of flow.

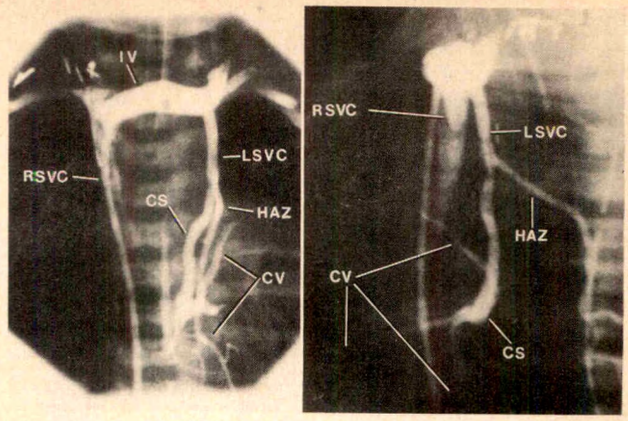

FIGURE 1. Selective left superior vena cava (LSVC) angiogram in a patient with atresia of the coronary sinus (CS) ostium shown in anteroposterior (**left**) and lateral (**right**) projections. Contrast filled the coronary veins (CV), LSVC, innominate vein (IV) and right superior vena cava (RSVC). No contrast entered either atrium. After injection, contrast was observed draining in a retrograde fashion from LSVC to IV to RSVC to right atrium. HAZ = hemiazygos vein.

Although this anomaly is believed to be of little functional significance,[2] diagnosis may be important before the surgical correction of associated cardiovascular abnormalities. A persistent left SVC and innominate vein recognized during preparation for cardiopulmonary bypass may be clamped or ligated.[3] Interruption of the sole route of cardiac venous return could have disastrous consequences such as ischemia or coronary arterial or venous thrombosis.

Contrast-Enhanced Cine Computed Tomography for Diagnosis of Right Coronary Artery to Coronary Sinus Arteriovenous Fistula

ROBERT M. MacMILLAN, MD
ALI SHAHRIARI, MD
SUMITHISENA, MD
BARBARA K. FENDER, BSRT
VLADIR MARANHAO, MD
DONALD CLARK, MD

Until recently, computed tomography (CT) could not be applied to the heart because of relatively slow exposure speeds of 1 to 5 seconds, which is not long enough to achieve adequate temporal resolution. With the development of the Cine/CT C-100® scanner (Imatron), multilevel 50-ms exposures can be obtained using peripheral intravenous bolus injections of contrast medium for image enhancement.[1] Resolution of cardiac anatomy in transverse 8-mm slices may provide diagnostic information not available by other techniques. The CT findings of a large right coronary artery to coronary sinus arteriovenous fistula are presented.

A 54-year-old man who had been followed for "mild" valvular heart disease for 10 years was admitted for evaluation of squeezing midsternal chest pressure radiating to the left arm, associated with dyspnea and provoked by physical exertion or psychological stress. Rest or nitroglycerin relieved the pain. The radial pulse was 54 beats/min and regular, and blood pressure 140/90 mm Hg in both arms, supine. There was no neck vein distention at 30° and the carotid pulses were normal. The cardiac apex impulse was in the sixth space in the anterior axillary line. There was a systolic left ventricular lift. The first heart sound was normal. The second heart sound was split but not fixed. A harsh grade 3/6 pansystolic murmur heard loudest in the sitting postion at the third left sternal border was increased by squatting and decreased with standing and Valsalva maneuver. A grade 2/6 diastolic decrescendo murmur was heard best at the same location. There were no gallops. An electrocardiogram revealed sinus bradycardia (52 beats/min), unifocal ventricular premature complexes, left anterior hemiblock and nonspecific ST-T abnormalities. There was mild cardiomegaly by chest radiograph. Echocardiography revealed slight left ventricular dilatation. First-pass radionuclide angiography

From the Deborah Heart and Lung Center (Affiliate of the University of Medicine and Dentistry of New Jersey), 200 Trenton Road, Browns Mills, New Jersey 08015. Manuscript received March 11, 1985; revised manuscript received May 16, 1985, accepted May 17, 1985.

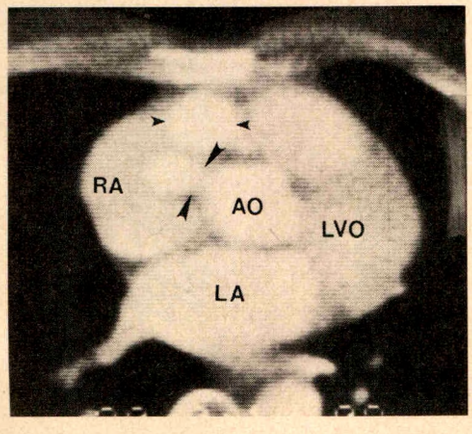

FIGURE 1. Cine CT C-100® scan at the level of the right coronary ostium. **Large arrows** mark the proximal right coronary artery arising from the aorta (AO) and **small arrows** mark a more distal segment. LA = left atrium; LVO = left ventricular outflow tract; RA = right atrium.

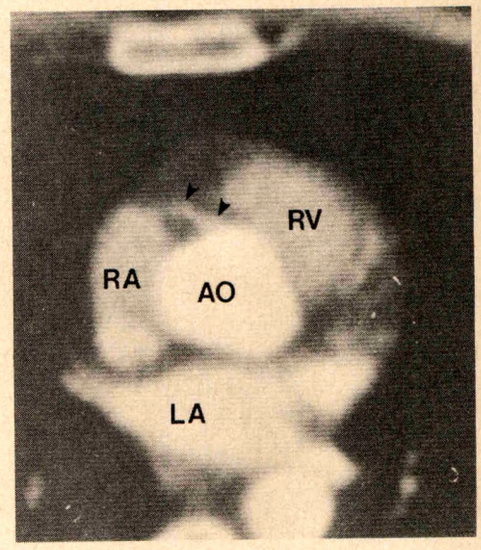

FIGURE 2. Cine CT C-100® scan showing origin and proximal segment of a normal right coronary artery (**arrows**). AO = aorta; LA = left atrium; RA = right atrium; RV = right ventricle.

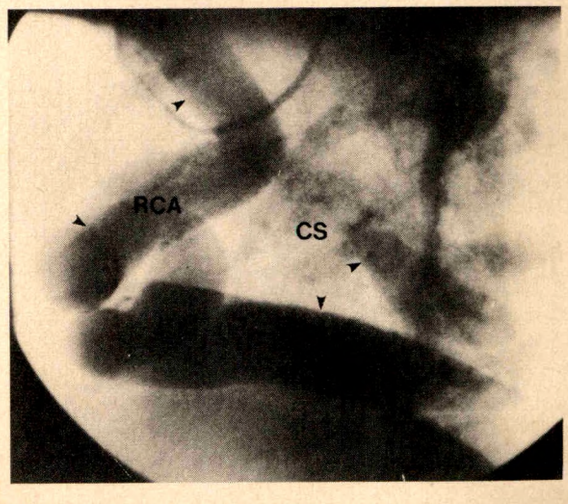

FIGURE 3. Selective injection of proximal right coronary artery (RCA) in left anterior oblique 60° projection. Note the markedly dilated and tortuous vessel (**arrows**), whose distal segment enters the coronary sinus (CS).

disclosed normal right and left ventricular ejection fractions with an unexplained concentration of tracer activity outside the right heart border. A treadmill stress test was stopped at 4 minutes owing to chest pain, but ST segments were nondiagnostic owing to ST-T abnormalities at rest. Cine-CT scan in the transverse plane at the level of the origins of the coronary arteries revealed a dilated right coronary artery (RCA) (1.4 cm in diameter) arising from the aorta (Fig. 1), as contrasted with a normal RCA (Fig. 2). Contiguous slices below the level of the origin of the RCA revealed the dilated RCA in its middle and distal segments, but the specific entry point into the coronary sinus was not seen. Analysis of flow curves demonstrates early reappearance in the right atrium and ventricle. CT scan also disclosed mild dilatation of the main pulmonary artery and left atrium. Cardiac catheterization revealed normal right and left ventricular function with no valvular heart disease. The left coronary artery was normal. The RCA arose from the normal location in the aorta but was enlarged and tortuous, eventually communicating with the coronary sinus (Fig. 3). A left-to-right shunt at the right atrial level was 1.3:1.

The Cine/CT C-100 scanner has been shown previously to visualize segments of the coronary arteries[2] and saphenous vein bypass grafts,[3] although sufficient image resolution does not yet exist to detect atherosclerotic narrowing. This report illustrates the contribution of the Cine/CT C-100 scanner to provide information not available using other noninvasive methods for the diagnosis of an uncommon congenital anomaly,[4,5] which caused clinical symptoms of angina pectoris.

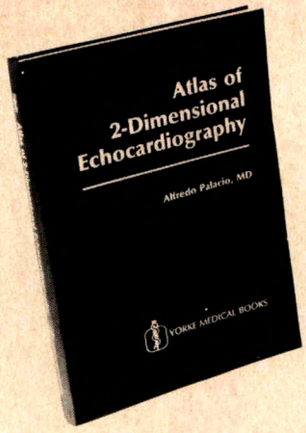
The First Practical Atlas of 2-D Echocardiography Ever Published



Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

HEWLETT-PACKARD'S NEW PAGEWRITER:

S I M P L E

Take a look at our new HP 4760 PageWriter Cardiograph. It's small, clean, simple. Yet, this unassuming package has the ability to meet all your ECG needs. Because it's easy to upgrade, from basic alphanumeric to measurement to interpretive. It's also easy to use. Operator prompts tell you about poor lead contact so you get an accurate trace the first time. And, you can start or stop printing at any time by pressing a single button. Best of all, PageWriter's small, lightweight design makes it easy to move from place to place.

A C C U R A T E

The new PageWriter is also extremely accurate. Automatic measurement capability means that the last ECG of the day is as accurate as the first. No more inconsistent, manual calculations. Plus, you can count on the analysis program in the interpretive module. It's the same one used worldwide by our customers to analyze over 5 million ECG's each year.

V E R S A T I L E

The basic PageWriter can be configured in a number of ways to handle just about any ECG application need. Order your PageWriter to meet today's applications. Then, field-upgrade your PageWriter when your needs change. Add automatic measurement. Add diagnostic interpretation. You can see how the PageWriter adapts. To any area of your hospital. To any ECG need.

A V A L U E

Simplicity. Accuracy. Versatility. Legendary HP reliability, service and support. Things you might expect from a high-priced cardiograph. But, the PageWriter is affordable. In fact, it's simply the best value in a cardiograph today.

Call **800-952-2212** and ask for our special "demo" PageWriter brochure. Or, write Hewlett-Packard Company, McMinnville Division, 1700 South Baker Street, McMinnville, OR 97128.

SIMPLY THE BEST VALUE IN A CARDIOGRAPH TODAY.

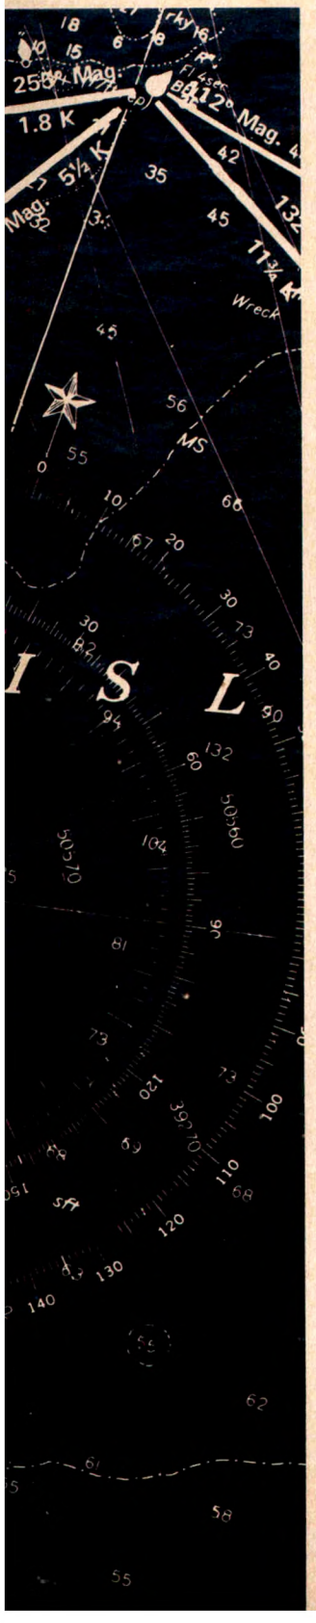
Initial therapy should star on the right course.

hypertensive patients



Minipress® for initial therapy
(prazosin HCl)

- Is effective when used alone
- Does not cause a significant incidence of sexual impotence, although it has been reported[1]
- Does not adversely affect blood lipids*[2]
- Does not lower heart rate, cardiac output or work capacity[3]
- Does not induce potassium wasting[1]
- Most common side effects with Minipress, generally mild and transient, are dizziness, headache, drowsiness, palpitations, and nausea. Syncope (sudden loss of consciousness) has been reported in about 0.15% of patients at the recommended initial dose of 1 mg.

*Minipress is not indicated for the treatment of hyperlipidemia.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

for Initial Therapy in Hypertension

Please see Minipress brief summary on following page

© 1983, Pfizer Inc.

Minipress®
(prazosin HCl) Capsules 1mg, 2mg, 5mg

Brief Summary
MINIPRESS® (prazosin hydrochloride) Capsules ***For Oral Use***
INDICATIONS: MINIPRESS (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: Minipress may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120–160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS. The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution. (See DOSAGE AND ADMINISTRATION.) Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.
If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.
Patients should always be started on the 1 mg capsule of MINIPRESS. The 2 and 5 mg capsules are not indicated for initial therapy.
More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure; namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS therapy.
Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS in pregnancy has not been established. MINIPRESS is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of MINIPRESS in children.
ADVERSE REACTIONS: The most common reactions associated with MINIPRESS therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.
The following reactions have been associated with MINIPRESS some of them rarely. (In some instances exact causal relationships have not been established.)
Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.
Cardiovascular: edema, dyspnea, syncope, tachycardia.
Central Nervous System: nervousness, vertigo, depression, paresthesia.
Dermatologic: rash, pruritus, alopecia, lichen planus.
Genitourinary: urinary frequency, incontinence, impotence, priapism.
EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.
Other: diaphoresis.
Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances the exact causal relationship has not been established because the baseline observations were frequently inadequate.
In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.
DOSAGE AND ADMINISTRATION: The dose of MINIPRESS should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:
Initial Dose: 1 mg two or three times a day. (See WARNINGS.)
Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.
Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.
OVERDOSAGE: Accidental ingestion of at least 50 mg of MINIPRESS in a two year old child resulted in profound drowsiness and depressed reflexes. No decrease in blood pressure was noted. Recovery was uneventful.
Should overdosage lead to hypotension, support of the cardiovascular system is of first importance. Restoration of blood pressure and normalization of heart rate may be accomplished by keeping the patient in the supine position. If this measure is inadequate, shock should first be treated with volume expanders. If necessary, vasopressors should then be used. Renal function should be monitored and supported as needed. Laboratory data indicate MINIPRESS is not dialysable because it is protein bound.
TOXICOLOGY: Testicular changes, necrosis and atrophy have occurred at 25 mg/kg/day (60 times the usual maximum recommended dose of 20 mg per day in humans) in long term (one year or more) studies in rats and dogs. No testicular changes were seen in rats or dogs at the 10 mg/kg/day level (24 times the usual maximum recommended dose of 20 mg per day in humans). In view of the testicular changes observed in animals, 105 patients on long term MINIPRESS (prazosin hydrochloride) therapy were monitored for 17-ketosteroid excretion and no changes indicating a drug effect were observed. In addition, 27 males on MINIPRESS (prazosin hydrochloride) alone for up to 51 months did not demonstrate changes in sperm morphology suggestive of drug effect.
HOW SUPPLIED: MINIPRESS is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).
More detailed information available on request.

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC
Henry N. Neufeld, MD, FACC

1978, 288 PAGES, 110 ILLUS., 1,000 REF.

Every Cardiologist, Internist, Pediatrician, Surgeon — Indeed, *Every Physician* — Should Have a Good Basic Knowledge of The Pre-excitation Syndrome. Here Are Just a Few Reasons Why This is so Essential:

- ⅓ of all pre-excitation cases are misdiagnosed.
- 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies on patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals

The 13 Chapters Are a Comprehensive Summary

1. General Considerations
2. The Electrocardiogram in the Pre-excitation Syndrome: Complexes and Configurations
3. The Electrocardiogram in the Pre-excitation Syndrome: Disturbances of Rate and Rhythm
4. Pathology
5. Noninvasive Methods of Investigation
6. Invasive Methods of Investigation
7. Prognosis
8. Treatment
9. Problems of Diagnosis — Some Illustrative Cases
10. Summary of Findings and Theories of Pre-excitation Syndrome
11. Concept of Interacting Structural and Functional Factors
12. Explanation of Some Phenomena of the Pre-excitation Syndrome by the Proposed Concept
13. Various QRS Patterns in the Different Forms of Pre-excitation

CLASSIFIED

CARDIOLOGIST (Non-Invasive) to associate with two board certified Cardiologists in twenty-two member multi-specialty clinic. Board certified or board eligible. Guaranteed salary with incentive bonus. Clinic is located in the heart of the Florida citrus industry and lake country. 1½ hours to either coast. Immediate drawing area—90,000. For additional information, send C.V. to: Box 465, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Critical Care Specialist—BC in IM plus BC/BE in Cardio. or Resp. or Critical Care. Part-time ICU Director, Part-time practice in multisubspec. IM Group. Medical School Affiliated. Upstate NY. Please reply to Box 455, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Cardiologist: BC-BE with experience and training in non-invasive procedures needed to join eastern Pennsylvania group practice. Opportunity to open a new suburban office devoted to clinical cardiology. Above average first year salary guaranteed. Please reply to Box 490, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Cardiologist, non-invasive, to join six man Internal Medicine Group in the Piedmont area of N.C. Excellent practice opportunity, good starting salary, ownership opportunity in one year. Immediate opening available. Please send curriculum vitae to: Box 460, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

THE MARSHFIELD CLINIC, a 225 physician multispecialty group practice, is seeking a second electrophysiologist to join an eight member cardiology department. The candidate must be Board certified or eligible in cardiology and have extensive training in electrophysiology and all aspects of arrhythmia evaluation and management. Send C.V. to W. Bruce Fye, M.D., Chairman, Cardiology Department, Marshfield Clinic, 1000 North Oak Ave., Marshfield, WI 54449.

THE QUINTON 3000 SYSTEM IS SO VERSATILE, IT CAN SUPPORT ITSELF.

Quinton
instrument co.

With the Quinton 3000 System, you'll never again leave your office when a patient needs a comprehensive stress test.

The Quinton 3000 System is easy to operate, and gives you more information, more accurately, than any other office stress testing equipment you can buy. In addition, you get it all at a better price—a price so good, in fact, that with two to three stress tests per month the system will pay for itself. Send us the coupon or call, toll-free, **800-426-0347** to see what words alone cannot express. We'll show you just how much the Quinton 3000 System can do for you. In Washington and Canada, Call **206-223-7373.**

London: A.H. Robins Medical Instruments Division, Mountcliff House 154 Brent Street, Hendon, London, N.W. 4, England

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work may also be submitted.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript, including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article; (3) miniabstract for Table of Contents that includes the full title and names of all authors; (4) abstract; (5) text; (6) references; (7) acknowledgment; (8) figure legends; and (9) tables. Number all pages in the above sequence, beginning with the title page as 1, the abstract as 2, and so on. (Leave the second title page and the miniabstract unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references), with at least 25-mm (1-inch) margins.

The second title page, on which the names and institution of the authors are omitted, gives the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is always honored.

TITLE PAGE, TABLE OF CONTENTS ABSTRACT AND MINIABSTRACT: For the **complete title page,** include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code.

Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 4 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage.

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

FIGURES: Submit 3 glossy, unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present," a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no."

BRIEF REPORTS: Brief Reports must be limited to no more than 3 text pages and 6 references. Longer ones usually will be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used in the body of the Brief Report.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor-in-Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

The AJC in December 1960

WILLIAM C. ROBERTS, MD

The AJC in December 1960 contained 27 articles, including a symposium on monoamine oxidase inhibitors, occupying 149 pages. This piece will comment on 1 article.

Brockenbrough and Braunwald[1] from Bethesda, Maryland, described a technique for introducing a catheter by the percutaneous method across the atrial septum, allowing angiography with injection of contrast material into either the left atrium or the left ventricle. Percutaneous puncture of the right femoral artery was carried out with a #16 gauge needle. A flexible coiled spring guide was then passed into the vein through the needle and then the needle was removed. A radioopaque polyethylene catheter 70 cm in length with an internal diameter of 1.15 mm and an outer diameter of 2.30 mm and with a curved distal end was introduced over the guidewire and advanced well into the femoral vein. The guidewire was then withdrawn. To straighten the loop and to facilitate placing the catheter in the right atrium, a stylet of 19-gauge hypodermic tubing, 5 mm shorter than the catheter, was inserted into and advanced with the catheter. After the catheter was positioned in the right atrium, the stylet was replaced by a 19 gauge transseptal needle, 71 cm in length. When the catheter and the needle had been appropriately positioned against the fossa ovale portion of the atrial septum, puncture of the septum was achieved by advancing the needle tip. Entry into the left atrium was confirmed by pressure measurements and the free withdrawal of oxygenated blood. The catheter was then advanced with the needle until both were within the left atrium. The catheter was then slipped over the held-steady needle and directed into the left ventricular cavity. The needle was then withdrawn. The left ventricular pressure was recorded and, if indicated, angiography performed. With this technique it made possible the performance of both right- and left-sided cardiac catheterizations using the same percutaneous puncture.

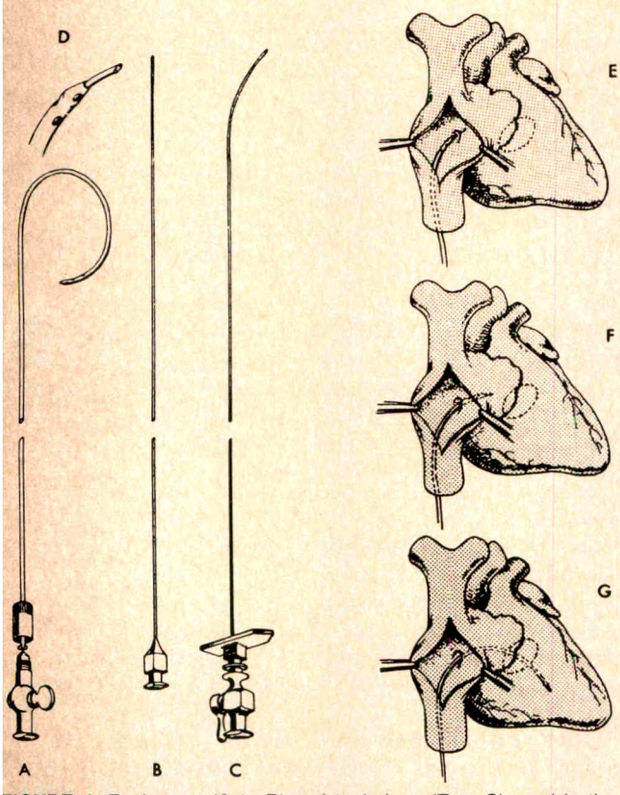

FIGURE 1. Equipment (**A** to **D**) and technique (**E** to **G**) used in the percutaneous method of transseptal left-sided cardiac catheterization. Reproduced with permission of the publisher.

Some Good Cardiologic Books

Most publishers of medical books send recently published books to editors of medical journals in hopes that their books will be reviewed, and, of course, reviewed favorably. During my 42-month tenure as editor of AJC, no book reviews have appeared, although recently received books are listed in the *Journal* about every 3 months. Picking the best of the medical books each year obviously is difficult. What is "best" to one person is not necessarily "best" to another. This piece lists a few of the better books that have crossed my editor's desk in 1985.

1. Braunwald E, editor *Heart Disease. A Textbook of Cardiovascular Medicine.* 2nd ed., Philadelphia: WB Saunders Company, 1984:1943, $95.00.

2. Hurst JW, ed. *The Heart, Arteries and Veins.* 6th ed., New York: McGraw-Hill Book Company, 1986:2193, $92.00.

These are the 2 most important books that a cardiologist can own. Because the subject matter in each book is written by different authors and because the material in each book is organized and presented quite differently, it is advantageous to own both books. Since each has a new edition every 3 years, it would appear most reasonable to purchase 1 book 1 year and the other book when its new edition appears.

The magnitude of the information presented in these 2 books is astounding and a tribute to the writing and organizational skills of the 2 editors. The Braunwald book weighs 4,380 grams, contains 1,943 pages with a maximum of 1,050 words per page, 57 chapters (25 of which were authored or coauthored by Braunwald) written by 51 authors, 15,112 references, 1,193 figures and 252 tables. The Hurst book weighs 3,260 grams, contains 2,193 pages with a maximum of 850 words per page, 140 chapters (8 of which were authored or coauthored by Hurst) written by 183 authors, 11,083 references, 1,005 figures and 199 tables.

3. Kirklin JW, Barratt-Boyes BG. *Cardiac Surgery. Morphology, Diagnostic Criteria, Natural History, Techniques, Results, and Indications.* New York: John Wiley & Sons, 1986: 1572, $150.00.

Absolutely magnificent book! As Dwight McGoon says in the foreword: "Perhaps you are like me in having fancied at one time or another of someday being able to encompass the entire body of essential information of a selected specialty and then 'wrap it up' into a skillfully coordinated, comprehensive, concise compendium. Increasingly rare are the occasions when that fantasy can be transformed into reality. Indeed, for cardiac surgery, such an accomplishment may never again occur after this book. This is especially true if an aspiring author is also required to be a principal contributor to essentially every frontier of progress in the entire specialty. Thus, from its very inception, this book has been unique. . . . The entire expanse of cardiac surgery seems to be here, laid out in the same crisp, logical, fully documented style that we have all come to recognize and respect in the many other reports, lectures, and publications provided by these particular authors."

This book has only 2 authors and each chapter reflects their combined outstanding authority on that subject. This book is a must for all physicians and surgeons involved in caring for persons with cardiac disease. It is one of the very best medical books ever published! I confidently predict that another edition of it will never appear. It is a classic from the beginning.

4. Crawford ES, Crawford, JL. *Diseases of the Aorta Including an Atlas of Angiographic Pathology and Surgical Technique.* Baltimore: Williams & Wilkins, 1984: 401, $135.00.

It is ideal, of course, when *the* recognized authority in a field authors a book on his (her) area of expertise. Such is the case in the above book. "Diseases of the Aorta" is primarily an atlas with magnificent color drawings by Perrin Sparks Smith. The drawings depict most aortic diseases, their varying appearances, and the techniques available for their surgical treatment. Although the book lacks computed tomography and echocardiographic observations, it nevertheless is masterful and should be owned by all surgeons who operate on patients with aortic disease. What pride the senior author must feel for his son to be a coauthor.

5. Wilcox BR, Anderson RH. *Surgical Anatomy of the Heart*. New York: Raven Press (published by special arrangement with Gower Medical Publishing), 1985: 148, $55.00.

This book is a color atlas combining photographs of normal and congenitally malformed hearts with accompanying color and line diagrams with appropriate text. The book combines efforts of a cardiac surgeon (Ben Wilcox) and a cardiac morphologist (Bob Anderson). The result is a splendid book. It actually concerns only the normal and the congenitally malformed heart and therefore its title is not fully descriptive of its contents. This book should be in the library of surgeons who operate on patients with anomalies of the heart and great vessels.

6. King SB III, Douglas JS Jr. *Coronary Arteriography and Angioplasty*. New York: McGraw Hill Book Company, 1985:478, $70.00.

Spencer King and John Douglas have lived in the cardiac catheterization laboratory for a number of years, the last 5 of which were working with the late Andreas Gruentzig, and this book shows that they know what they were doing.

7. Cohn PF, editor. *Diagnosis and Therapy of Artery Disease*. 2nd ed. Boston: Martinus Nijhoff Publishing, 1985:517, $69.50.

8. Connor WE, Bristow JD, editors. *Coronary Heart Disease. Prevention, Complications and Treatment*. Philadelphia: J.B. Lippincott, 1985:461, $45.00.

9. Califf RM, Wagner GS, editors. *Acute Coronary Care, Principles and Practice*. Boston: Martinus Nijhoff Publishing, 1985:556, $52.50.

All 3 books are multiauthored with inherent advantages and disadvantages of each. None of these should be purchased until both the Braunwald and Hurst books have been bought.

10. Ellestad MH. *Stress Testing. Principles and Practice*. 3rd ed. Philadelphia: FA Davis Company, 1986: 564, $48.00.

Almost certainly the best book on this subject.

11. Feigenbaum H. *Echocardiography*. 4th ed. Philadelphia: Lea & Febiger, 1986:685, $55.00.

The first edition of this classic appeared in 1972 and a new edition has appeared every 4 or 5 years since. This new edition contains more 2-dimensional echocardiograms and also a good number of Doppler echocardiograms. This is the first echo book to buy.

12. Nanda NC, editor. *Doppler Echocardiography*. New York: Igaku-Shoin, 1985:522, $55.00.

An authoritative up-to-date book on a rapidly expanding subject.

13. Wenger NK, Hellerstein HK, editors. *Rehabilitation of the Coronary Patient*. 2nd ed. New York: John Wiley & Sons, 1984:563, $37.50.

14. Pollock ML, Schmidt DH, editors. *Heart Disease and Rehabilitation*. 2nd ed. New York: John Wiley & Sons, 1986:788, $47.50.

Two good and different multiauthored books on an important subject. I also like the book: Peterson LH. *Cardiovascular Rehabilitation. A Comprehensive Approach*. New York: MacMillan, 1983:363, $48.00.

15. Zipes DP, Jalife J, editors. *Cardiac Electrophysiology and Arrhythmias*. Orlando: Grune & Stratton, 1985:567, $98.50.

A book honoring Gordon K. Moe and having 174 contributors.

16. Freedom RM, Culham JAG, Moes CAF. *Angiocardiography of Congenital Heart Disease*. New York: MacMillan, 1984:691, $125.00.

Surely the best book on this subject.

THE ORIGIN OF GIANT U WAVES

Giant repolarization waves such as those reported by Shimoni et al[1] are virtually pathognomonic of a preceding syncope.[2] They may be indistinguishable from similar waves occasionally seen in Romano-Ward syndrome, with similar postsyncopal alternans.[3,4] I would suggest that the striking electrocardiographic abnormalities reported by Shimoni et al are more likely to have been caused by neural mechanisms than by the modest electrolyte disturbance documented after the patient's syncope. The electrolyte-dependent QT-interval prolongation, admittedly, provoked the torsades de pointes observed, with syncope; but the ultimate electrocardiographic appearances should have been attributed to syncope itself.

REPLY: Giant repolarization waves, as described in our case report, are indeed indistinguishable from similar waves seen in Romano-Ward syndrome with postsyncopal alternans. However, these waves are not exclusively pathognomonic of a preceding syncope. Lopez et al[1] stated that "aside from the T wave alternans that appears in the congenital long Q-T syndrome, the acquired alternans has been observed in various clinical situations." Most of these "situations" are virtually low-serum electrolyte levels such as hypocalcemia, hypokalemia or hypomagnesemia. Schamroth[2] described giant repolarization waves (but without alternans) after recurrent syncopal attacks in patients with organic heart disease. Our patient had no evidence of organic heart disease when she entered the hospital, nor when she left it. Her striking electrocardiographic abnormalities regressed concomitantly with the gradual normalization of serum electrolyte levels.

As for the electrolyte levels (calcium = 6.5 mg/dl; potassium = 2.9 mEq/liter), most of the cases reviewed were reported to have T-wave alternans in association with milder electrolyte deficiencies.[1,3–6] Moreover, Mullican and Fisch[7] reported a case of giant U waves with postextrasystolic alternans that he believed was due to potassium depletion, despite a low-normal serum potassium level (3.7 mEq/liter). He suggested that the electrocardiographic changes may be a poor index of the plasma level of potassium. In conclusion, (1) postsyncopal giant U waves without alternans are seen in patients with organic heart disease; (2) postsyncopal alternans of giant repolarization waves occurs in Romano-Ward syndrome, but has not been described in patients without any organic heart disease; (3) the occurrence of episodic T (or U)-wave alternans in various clinical conditions suggests that several mechanisms may be involved[8]; and (4) electrolyte disturbances may cause giant U-wave alternans even in the absence of organic heart disease, as described in our case report.

ICE-WATER WASHCLOTH RATHER THAN FACIAL IMMERSION (DIVING REFLEX) FOR SUPRAVENTRICULAR TACHYCARDIA IN ADULTS

We read the letter of Sacks and Smith[1] in which they described ice-water washcloth treatment of supraventricular tachycardia (SVT) in infants. At about the same time we read the letter, we treated a 45-year-old man in whom SVT developed. When we saw him in the emergency room the SVT (rate 180 beats/min), which he experienced for the first time, had lasted for about 2 hours and he had received no treatment. We tried the "diving reflex" as the initial treatment. When the patient sat up in bed for facial immersion many artifacts appeared on the monitor screen. To avoid these artifacts, a washcloth was immersed in ice-water for several minutes, wrung-out and applied to the patient's face after he assumed the recumbent position. The patient was instructed to hold his breath in inspiration. Twenty seconds later sinus rhythm appeared on the monitor screen and on the electrocardiographic strip. SVT did not recur. Prophylactic verapamil was prescribed and he was discharged 24 hours after the episode. This experience suggests that an ice-water cloth applied for a brief period to the face of an adult with SVT may safely and effectively restore sinus rhythm.

POSTEXTRASYSTOLIC POTENTIATION DURING ACUTE MYOCARDIAL INFARCTION: PREDICTING PRESENCE OF VIABLE MYOCARDIUM

The study of Hodgson et al[1] suggests that postextrasystolic potentiation (PESP) may be useful during acute myocardial infarction (AMI) as a marker of ischemic but viable myocardium that may be salvaged by reperfusion. However, data from our laboratory[2] suggest alternative explanations of their findings. First, Figure 2 in their study implies that as a group, the ischemic segments had greater PESP than nonischemic segments. Although raw data are not presented, it appears that the function of some of the nonischemic segments may have deteriorated with premature stimulation. These findings have not been observed in experimental preparations using sonomicrometers[3] and 2-dimensional echocardiography[4] and suggest that the results observed by Hodgson et al may have been importantly influenced by the normalized floating axis angiographic analysis of endocardial motion used by the investigators.

Second, their method of regional analysis divided the ventricle into 3 large areas, which may have concomitantly embraced both ischemic and nonischemic zones. Because the study was of ventricular function only, conclusions regarding the state of ischemia of myocardium demonstrating PESP can only be inferred. Was this myocardium truly ischemic and did salvage of it by reperfusion account for the late return of function observed? "Tethering" or dyskinesia of nonischemic regions adjacent to ischemic regions has been well described in experimental animals[5] and humans.[6] Our study, which used contrast 2-dimensional echocardiography to delineate the region at risk, also demonstrated tethering of nonischemic myocardium and, furthermore, localized the PESP response to these regions. PESP was

* Letters (from the United States) concerning a particular article in the *Journal* must be received within 2 months of the article's publication, and should be limited (with rare exceptions) to 2 double-spaced typewritten pages. Two copies must be submitted.

ost in the central 50% of the region at risk ıfter only 5 minutes of ischemia and was lost n the remainder of the region at risk after 30 minutes of ischemia. From 30 minutes on, he only dyssynergic regions demonstrating PESP were the nonischemic, nonjeoparlized regions bordering the infarct zone. This is not to say that ischemic myocardium annot show persistent PESP[4]; however, the everity of ischemia in these regions is probbly no worse than moderate and may not e of sufficient degree to produce significant nfarction. In any case, such myocardium ccupies only a small minority of the region t risk in the usual canine infarction. Most f the region at risk of AMI, even though till viable, did not demonstrate PESP in ur study. Our data suggest caution in aplying PESP to determine whether patients re candidates for an intervention during AMI.

Finally, our analysis of the tethered nonschemic adjacent zones suggests an alternaive explanation for the late improvement in egions demonstrating PESP during AMI een by Hodgson et al.[1] We found a tendency for improvement in unstimulated systolic hickening in tethered zones over the 6-hour uration of our experiment. These data sugest that the late improvement in function een by Hodgson et al was not necessarily ue to salvage of ischemic myocardium but ıay reflect a natural tendency of dysfuncional tethered myocardium to improve inependent of intervention.

REPLY: The intent of our study was to letermine if interventional ventriculography could provide useful predictive data oncerning changes in left ventricular wall notion after successful thrombolytic coroary reperfusion. Analyzing both collateral low and PESP allowed us to identify 76% of egments that had improved regional wall notion after successful, sustained reperfuion. Force et al are correct in pointing out hat we have not conclusively demonstrated that the mechanism for chronic improvement in these segments is related to salvage of ischemic myocardium. This can only be accomplished by evaluating reperfusion in this subgroup of patients in a prospective randomized study.

Regional wall motion was determined using an area ejection fraction to overcome the poor reproducibility of other quantitative programs.[1] Sheehan et al[2] confirmed our findings using a centerline method of regional wall motion analysis.[3] They have further confirmed that compensatory hyperkinesia decreases in the nonischemic segments in the postextrasystolic beat.[2]

Experimental studies provide conflicting data concerning the presence of PESP in ischemic myocardium. Boden et al[4] and Sakamaki et al[5] demonstrated PESP to be maintained in ischemic myocardium up to 4 hours after coronary occlusion. Crozatier et al[6] and Force et al[7] conversely suggest that PESP is abolished within 5 minutes of coronary occlusion. These discrepancies may be explained by the methods used to measure wall motion. Strain gauges and 2-dimensional echocardiographic measurements, reflecting subepicardial and transmural wall motion, demonstrate that PESP is maintained. Ultrasonic crystals that reflect subendocardial wall motion demonstrate the loss of PESP early after occlusion. These findings suggest to us that the central, maximally ischemic zone rapidly loses inotropic reserve and rapidly undergoes myocardial necrosis. Myocardium with less severe ischemia, such as the subepicardium, has PESP maintained during prolonged ischemia.

Our findings suggest that interventional ventriculography accurately identifies marginally ischemic myocardial segments where thrombolytic reperfusion is most likely to result in myocardial salvage.

CORONARY ANGIOPLASTY IN MYOCARDIAL INFARCTION

The report by Papapietro et al[1] on percutaneous transluminal coronary angioplasty (PTCA) after administration of intracoronary streptokinase ignores the previous studies on this subject. To our knowledge, Meyer et al[2] first described the feasibility of PTCA in the setting of acute myocardial infarction (AMI) along with the clinical results in a group of 21 patients. This article was followed by a case report from our institution.[3]

Because reocclusion of the infarct-related vessel occurred in 4 of the 13 patients successfully dilated, Papapietro and associates[1] concluded that PTCA may not prevent rethrombosis. This is at variance with our finding[4]: The reocclusion rate demonstrated by angiography before discharge was reduced from 17% to 7% when PTCA was performed immediately after thrombolysis in the presence of a severe residual stenosis (58% diameter stenosis, as assessed from quantitative coronary angiography). This discrepancy can be explained by (1) the small numbers in both studies, and (2) the higher reocclusion rate after dilatation of a totally occluded vessel as in 2 of their cases.[5] Another major issue is the selection criteria for this procedure. Less severe underlying stenoses (50% diameter reduction) are not infrequent after thrombolysis (in one-third of the patients in our series[4]). By analogy with PTCA in stable angina, dilating mild lesions might expose the patients to the unnecessary risk of restenosis.[6] Furthermore, the incidence of restenosis and reinfarction are clearly related to the severity of the residual obstruction.[5,7] Thus, selection of the patients should be based on objective criteria rather than on visual evaluation of the angiograms. These and many other issues need to be addressed before the role of PTCA in the management of patients with AMI can be established.

MULTIPLE RISK FACTOR INTERVENTION TRIAL

The Multiple Risk Factor Intervention Trial Research Group presented a detailed and much needed further explication of their results, in particular the relation of baseline electrocardiographic abnormalities at rest and mortality.[1] Their results appear to show an excessive relative risk (1.67) for the special intervention (SI) group among those who had both an abnormal electrocardiogram at rest and systemic hypertension. In fact, as seen at the bottom of Table II, this is the only 1 of the 4 possible combinations of electrocardiograms and blood pressure at rest that was clearly against the SI group. (All nonhypertensive and hypertensive patients without baseline electrocardiographic abnormalities showed differences in the opposite direction). The investigators ascribed this mainly to sudden death within the first hour and invoked the presence of certain medications in the SI group. They further report that by Cox regression the difference between men with and without electrocardiographic abnormalities at rest is "nominally significant ($p = 0.02$)."

I wonder if the significant-appearing difference is clinically significant? After all, p values are merely indications of the strength of the evidence against the null hypothesis (no treatment difference) and cannot be considered as direct proof of a treatment effect. Moreover, a statistical evaluation for interaction in the 4 subgroups under consideration may or may not support the null hypothesis. As a non-statistician I would not wish to attempt this, but the authors may wish to examine that aspect.

David H. Spodick, MD, DSc
Boston, Massachusetts
18 February 1985

1. Multiple Risk Factor Intervention Trial Research Group. Baseline rest electrocardiographic abnormalities, antihypertensive treatment, and mortality in the Multiple Risk Factor Intervention Trial. Am J Cardiol 1985;55:1–15.

REPLY: We appreciate Spodick's comments. He has accurately summarized the main between-group (SI/Usual Care) findings we reported, and poses 2 further questions. To address first his second and more straightforward question: We had previously tested the 4-group interaction, and it does not reach conventional statistical significance ($p = 0.12$). Because this and a number of other analyses presented are not nominally significant, we would rephrase his other question as follows: If the adverse effect is real (e.g., not due to random error), is it of a magnitude to be clinically significant? We would be inclined to answer in the affirmative: A relative risk of 1.67 for coronary artery disease mortality or a relative risk of 2.34 for sudden death would be clinically significant. Whether the adverse effect is real is best answered by replication in other clinical trials. The available analyses from 2 previous trials show trends similar to the findings of the Multiple Risk Factor Intervention Trial for their coronary end points, but again, no definitive results.[1,2] Thus, for now, determination of the significance of these observations will have to rest on clinical judgment.

ASSESSMENT OF AMRINONE

I am pleased that Firth et al[1] completed their study comparing the inotropic and vasodilator effects of amrinone and isoproterenol. In May 1982, my co-workers and I studied the first patient of a group in whom we intended to compare these 2 agents. This and other trials of amrinone in our laboratory were cut short when the drug manufacturers unilaterally and without warning removed stocks of the drug held in our hospital on June 11, 1982. The removal of the drug by the pharmaceutical company occurred 1 week after I had presented at the Royal Society of Medicine preliminary data on the hemodynamic effects of intracoronary amrinone[2] and the effects of amrinone on isolated human myocardium and vessels.[3]

The study by Firth et al is yet another example in which investigators have failed to confirm that amrinone has positive inotropic effects.

According to the prescribing information on amrinone (Inocor®) supplied in the USA by its manufacturers (Winthrop-Breon), "amrinone lactate, represents a new class of cardiac inotropic agents ... indicated for the short term management of congestive heart failure." The data do not support many of the claims made by the manufacturers about this drug. In particular, the evidence does not support the view that amrinone is a positive inotropic agent in patients with congestive heart failure.

The drug may or may not be a positive inotropic agent in normal animals, animals with heart failure or humans without heart failure. This does not matter to the clinician. The drug may have effects on filling pressures and cardiac index in patients with heart failure as do all other vasodilators, and most are safer than amrinone. For the manufacturers to claim that a drug is an inotropic agent for use in patients with heart failure, they must show that it improves contractility in patients with heart failure, and drug-licensing authorities should be certain that they have adequately demonstrated the proof.

There are only 9 studies relevant to whether or not amrinone is a positive inotropic agent in patients with impaired left ventricular function.[1–9] Three studies[4–6] did demonstrate an increase in dP/dt max after the drug. However, these studies were small, did not seek to demonstrate a dose-response relation of altered contractility with serial doses of the drug and were biased toward finding an increase in contractility by virtue of their design as we have previously discussed.[7]

There have been 4 studies,[1,7–9] each with larger numbers of observations, in which a dose-response relation was sought. No evidence was found that amrinone improved many of indexes of contractility. Two studies compared amrinone with intravenous β-adrenergic agonists and found that amrinone produced no change in contractility, but dobutamine[8] and isoproterenol[1] produced dose-related increases. Another study compared amrinone with the pure vasodilator, nitroprusside, and found no significant difference.[9] In this study, increases in contractility after amrinone administration in a few patients were related to metabolic changes which suggested that they were the result of catecholamine release. Such catecholamine release commonly occurs with phosphodiesterase inhibitors like amrinone. Furthermore, amrinone does not alter the left ventricular end-systolic pressure-volume relation.[7]

Intracoronary infusions of amrinone[2] and a study that investigated the effect of amrinone on isolated human myocardium[3] do not suggest that amrinone has a positive inotropic effect in patients with cardiac failure.

It is therefore difficult to understand how amrinone has attained an undeserving reputation as an inotropic agent in patients with heart failure and why drug licensing authorities have been prepared to accept inadequate proof of efficacy.

EVALUATION OF CORONARY COLLATERAL CIRCULATION

A recent study by Elayda et al[1] discussed the relation between angiographic quality of coronary collateral circulation and preservation of left ventricular (LV) segmental wall motion. Analysis of LV regions supplied by 190 totally occluded arteries revealed no significant contractility differences between regions supplied by "good" collaterals and those supplied by "poor" collaterals. This conclusion differs substantially from that drawn by an article[2] of mine in 1974, which concluded that segmental LV wall motion was significantly better in those areas supplied by good collaterals. The reason for this difference is, I believe, that Elayda et al used inappropriate criteria in judging the adequacy of collateralization.

There is no doubt that it is difficult to angiographically gauge the quality of coronary collateral circulation. We lack a reliable quantitative method of accomplishing this, and therefore most such judgments end up being subjective. In my earlier study, I used the angiographic caliber of the distal segment of the occluded coronary artery as the primary criterion for determining adequacy of collateralization. This was based on the assumption that if the distal segment receives inadequate collateral flow, it will be underfilled and will therefore constrict. One can frequently observe the converse of this situation—that when normal flow is restored to such a vessel by coronary bypass, the distal segment dilates back up to its original caliber. Elayda et al instead used the degree of opacity of the distal segment as their sole criterion of collateral adequacy. In their study, collaterals were considered "good" if the opacity of the distal segment was 50% or more of the proximal segment, and "poor" if the opacity of the distal segment was less than 50% of the proximal segment. Of all the criteria one might choose to evaluate adequacy of collateralization, this seems to be the least reliable. The opacity of the distal segment of an obstructed coronary artery is directly related to the concentration of contrast material in the blood reaching that distal segment through collateral flow. If, as is frequently the case, a distal segment receives collateral flow from both the right and left coronary systems, its opacity will virtually always be reduced for the simple reason that coronary arteriography is performed by injecting only a single coronary artery at a time. For example, assume a patient with a dominant right coronary system has complete obstruction of the mid-right coronary artery, with well-developed collaterals supplying its distal segment from both the proximal portion of the right coronary artery and branches of the left anterior descending and circumflex arteries. During right coronary arteriography in such a case, the distal right coronary segment will appear poorly opacified because of inflow of unopacified blood from the branches of the left coronary system. On the other hand, when one performs a left coronary arteriogram in this patient, the distal right coronary artery will again appear poorly opacified because of inflow of unopacified blood from the proximal right coronary artery. Thus, although collateral circulation might be excellent in such a case, it would be classified as poor, using the criteria of Elayda et al, because of reduced opacity of the distal segment. There are other radiographic problems as well—variations in optical density of the cine film related to function of the automatic brightness control of the generator, presence or absence of soft tissue shadows caused by the diaphragm or patient habitus, etc. In view of this fallacious selection of criteria for assessing collateral quality, it is doubtful that their conclusion is justified. The authors cite a number of other supporting references; however, all of these were published before 1974 and many used similarly questionable methods of evaluation of collateral circulation.

Since publication of my article in 1974, other studies have been reported[3–7] which support the concept that collateral circulation does exert a protective role in preservation of LV myocardial viability and contractility. This does not imply, however, that collaterals can completely ameliorate the effects of myocardial ischemia or provide absolute protection against the development of myocardial infarction.

FREQUENCY OF PERICARDIAL EFFUSION BY M-MODE ECHOCARDIOGRAPHY AFTER ACUTE MYOCARDIAL INFARCTION

Kaplan et al[1] made a substantial contribution to the understanding of pericardial involvement during acute myocardial infarction. I have several questions including some points that they might wish to amplify to elucidate the message of their very worthwhile investigation. Although the text is carefully worded and I think no critical reader could make many misinterpretations, I wonder if pleuritic pain is enough of a criterion to decide that a patient has pericarditis. Like Kaplan et al, we frequently see such pain, but usually without a pericardial rub (which we use to confirm the diagnosis) and, of course, nearly always in the absence of a diagnostic electrocardiogram.[2] This report, in common with so many others, omits electrocardiographic changes and I assume that these were either rare or nonexistent. Indeed, there is no reason why this kind of pericarditis—limited to the infarct—should be associated with a typical ubiquitous ST-T elevation. Without a pericardial rub, therefore, pleuritic pain equally might represent pleuritis or pulmonary embolism, thus, the question arises: How many patients had signs of *pleural* effusion either on chest x-ray or in the echocardiogram? Kaplan et al themselves raise the question of epicardial fat being responsible for overdiagnosis of pericardial effusion and, of course, this could not be verified without a CT scan. Some smaller effusions could be due to congestive heart failure and one wonders about that datum among their patients. Their results with the distribution of pericardial rubs, site of infarction, and Q wave versus non-Q infarct are in accordance with ours.[2] On the other hand, there was an unusual predominance of female patients (10 of 16) among the patients with pericardial effusion, although the overall male dominance in pericarditis (27 of 16) was evident. Finally, of the small group that had pericardial rubs (8 of 43), how many were women?

These remarks are made to seek amplification rather than as direct criticism of a highly instructive, valuable investigation.

2. **Krainin FM, Flessas AP, Spodick DH.** Infarction-associated pericarditis: rarity of diagnostic electrocardiogram. N Engl J Med 1984;311:1211–1214.

REPLY: Spodick's comments on our study are appreciated and raise a number of interesting questions. We agree that the cause of pleuritic chest pain after acute myocardial infarction (AMI) may be difficult to discern. In our diagnosis of clinical pericarditis, we included only patients with pleuritic pain that was clearly lessened by sitting up. None of our patients had pleural effusions, evidence of pulmonary emboli or chest wall tenderness. Likewise, no patient had electrocardiographic changes suggestive of pericarditis. Given the evanescent nature of pericardial friction rubs, in the setting of AMI we believe it is justifiable to diagnose clinical pericarditis by the presence of a classical symptom complex only. In our report 8 of the 12 patients with a diagnoses of pericarditis had rubs.

Our results suggest that the presence or absence of a pericardial effusion on M-mode echocardiography is not helpful in the differential diagnosis of pleuritic chest pain, probably because the pericarditis of myocardial infarction is a localized area of inflammation that may not be picked up by this limited technique and because there

may well be other causes for the presence of a pericardial effusion. For example, we agree with Spodick that some pericardial effusions after AMI may be a manifestation of congestive heart failure. This is indirectly supported by our finding that pericardial effusions are associated with a higher Killip classification and greater creatine phosphokinase release.

We share Spodick's interest in the greater frequency of pericardial effusions in females (10 of 16) vs males (6 of 27). This may reflect the finding of the Framingham study, that posterior extra echocardiographic spaces are present more often in women than in men.[1] We found a similar percentage of pericardial rubs in women (3 of 16) and men (5 of 27), but the numbers are too small to make conclusions with regard to differences in frequency between sexes.

SUBCRITICAL CORONARY STENOSIS

The study by Brown et al[1] does not address a few points. Although the data are presented as if 2 groups of patients were being compared (the separating point being 20% coronary stenosis), 78 patients in the second group consisted of 74 persons with normal coronary arteries. These 74 therefore cannot be considered patients, and the numbers to be used for comparison should be 22 and 4, not 22 and 78. Even if the group of 74 persons comprised a subset of patients with heart disease *not* related to coronary stenosis and could still result in an abnormal thallium scan (which the authors do not elaborate on), they would still be comparing 2 different etiologic factors.

Currie et al[2] demonstrated that supine exercise is much more likely to result in a positive electrocardiographic stress test at a smaller workload than upright exercise; such a positive study revealed greater ST-segment deflections than the upright group. The study by Brown et al used both forms of exercise and used different end points (chest pain for upright and fatigue for supine exercise). With so many variables, they are not justified in reaching the conclusion that the 2 methods did not differ with regard to results.

Patients with "stress-induced" chest pain (as opposed to chest pain elicited on the treadmill) are described as having a higher incidence of abnormal thallium scans than those without. This contradicts their Methods section, which states that these were 100 consecutive patients who were studied because of chest pain. Were these patients' pain not related to exertion, was coronary spasm considered, and was ergonovine provocation study performed?

As an angiographer, I always maintain that visual "reading" of an angiogram may underestimate the physiologic significance of a lesion. However, I do not think that Brown et al proved that fact using their data.

Murthappa N. Prakash, MD
Bronx, New York
5 March 1985

1. **Brown KA, Osbakken M, Boucher CA, Strauss HW, Pohost GM, Okada RD.** Positive exercise thallium-201 test responses in patients with less than 50% maximal coronary stenosis: angiographic and clinical predictors. Am J Cardiol 1985;55:54–57.
2. **Currie PJ, Kelly MJ, Pitt A.** Comparison of supine and erect bicycle exercise electrocardiography in coronary heart disease: accentuation of exercise-induced ischemic ST depression by supine posture. Am J Cardiol 1983;52:1167–1173.

REPLY: Our study did not simply compare exercise thallium-201 imaging in 2 groups of patients with <50% coronary stenosis. The primary analysis of data used stepwise logistic regression which examined multiple patient variables. This analysis demonstrated that percent maximal angiographic stenosis, as a continuum, was a significant determinant of a positive thallium study. When patients were divided into 2 groups, somewhat arbitrarily by their maximal narrowing, we found that those with >20% maximal stenosis had a higher incidence of positive thallium tests than those with ≤20%. Our observation that thallium defects corresponded to the myocardial territory supplied by the coronary artery with <50% stenosis supports our contention that such apparently minor angiographic disease may have true hemodynamic impact. We see no reason to separate further those with ≤20% stenosis from those with apparently entirely normal coronary arteries. In fact, resolution of qualitative angiography is probably inadequate to distinguish such groups reliably. All persons had presented for evalution of chest pain severe enough to warrant catheterization and can be considered "patients," and not necessarily representative of a normal population.

We agree that data exists suggesting that supine vs upright exercise may influence stress-induced electrocardiographic changes in patients with coronary artery disease. However, as indicated in Table I of our study, we found no difference in electrocardiographic ischemia, frequency of reaching 85% maximal predicted heart rate or several other important patient variables between supine vs upright stress. Furthermore, method of exercise was not a predictor of thallium defect when analyzed using logistic regression. Finally, the endpoint for both upright and supine exercise was fatigue. For all these reasons, we felt justified in pooling the data.

"Stress-induced chest pain," typical or atypical for angina pectoris, refers specifically to chest pain elicited during the treadmill or bicycle exercise. All patients were brought to medical attention because of previous complaints of chest pain.

COLD-INDUCED IMMERSION INJURY

Campbell and Jewitt[1] report a rare episode of frostbite in a 46-year-old woman during a cold pressor test—hand immersion to the wrist in 0-degree iced water for 4.5 minutes. From "first hand" experience, 4.5 minutes in 0-degrees water is a very painful stimulus. It is unclear why 4.5 minutes was the endpoint of the cold pressor test since physiologic endpoints were not specified. After performing over 100 cold pressor tests[2–4] (applying crushed ice to the hand and forearm or immersing the hand in iced water and terminating the test when mean arterial pressure increased at least 10 mm Hg, in all cases less than 3 minutes), our study teams have never observed local complications. Although cold pressor testing is not standardized, cardiologists should identify an endpoint, such as change in mean arterial pressure, to limit cold exposure and minimize patient discomfort.

We agree with the authors' speculation that β-adrenergic blockade may exaggerate cold pressor test responses.[2]

CORONARY ARTERY OCCLUSION SEVEN WEEKS AFTER ANGIOPLASTY SUCCESSFULLY MANAGED WITH REPEAT EMERGENCY ANGIOPLASTY

We read with interest the study of Materne et al.[1] We wish to report our own experience which further illustrates the unstable nature of an occluded artery treated with angioplasty, and its successful management.

A 52-year-old woman underwent elective coronary angiography for angina pectoris. A 60% midright coronary artery (RCA) stenosis diameter reduction was followed by a 99% stenosis (Fig. 1A). Percutaneous transluminal coronary angioplasty (PTCA) was electively scheduled for the next morning. Earlier PTCA intervention, however, became mandatory with the onset of severe chest pressure and acute inferior ST-segment elevation. This was 7 hours after initial elective angiography. A totally occluded mid-RCA (Fig. 1B) was dilated (Fig. 1C), leaving a 10% stenosis at the site of earlier occlusion, and the more proximal 60% stenosis noted above. Total CK peaked at 107 IU/liter. The patient was discharged taking aspirin, dipyridamole and nifedipine.

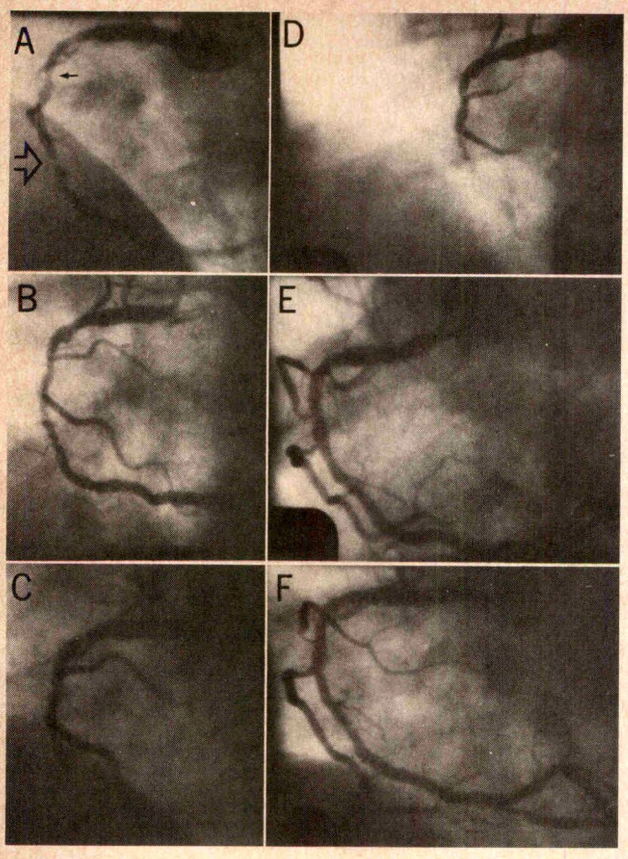

FIGURE 1. A, initial diagnostic angiogram of right coronary artery (left anterior oblique view) showing 60% stenosis (**small arrow**) and 99% stenosis (**large arrow**). **B,** right coronary angiogram (left anterior oblique view) showing acute occlusion of right coronary artery on evening of first hospital day. **C,** right coronary angiogram (left anterior oblique view) immediately after initial emergency percutaneous transluminal coronary angioplasty. **D,** 2 weeks. Right coronary angiogram (left anterior oblique view) after angioplasty of more proximal 60% stenosis. **E,** 7 weeks. Right coronary angiogram (left anterior oblique view) showing complete coronary occlusion at time of restudy. **F,** right coronary angiogram (left anterior oblique view) immediately after repeat emergency percutaneous transluminal coronary angioplasty.

Two weeks later, the patient was readmitted with recurrent angina at rest. Repeat angiography was unchanged in comparison to the post-angioplasty injections. Admission symptoms prompted angioplasty on the proximal 60% stenosis. This was reduced to a 10% stenosis, and the earlier angioplasty site remained widely patent (Fig. 1D). Previous medications were continued and the patient was discharged in satisfactory condition.

Seven weeks after the initial presentation, the patient was seen in the emergency room for acute, severe chest pressure, again associated with inferior ST-segment elevation. Angiography was repeated, and demonstrated total RCA obstruction at the site of the initial angioplasty (Fig. 1E). A 10% narrowing also was present at the more proximal PTCA site. Angioplasty was successfully repeated at the obstruction (Fig. 1F), and the total duration of chest pain was 2 hours. Intracoronary streptokinase (25,000 U) was administered to deter recurrent RCA thrombosis. The peak CK was 266 IU/liter. Radionuclide ventriculography at rest was performed 2 days later. The left ventricular ejection fraction was 61% and there were no regional wall motion abnormalities. Platelet aggregation studies and antithrombin III levels were normal. The patient continued to receive full-dose heparin therapy, and later therapy was converted to oral warfarin. Other discharge medications included dipyridamole and high-dose nifedipine.

This patient demonstrates that repeat coronary angioplasty may be successfully used for acute recurrent coronary arterial occlusion. Interim angiography confirmed arterial patency, and also in Materne's patient. Nonetheless, this was not predictive of a long-term satisfactory course.
